The global assessment report on BIODIVERSITY AND ECOSYSTEM SERVICES

ipbes

GLOBAL ASSESSMENT REPORT OF THE INTERGOVERNMENTAL SCIENCE-POLICY PLATFORM ON BIODIVERSITY AND ECOSYSTEM SERVICES

ISBN: 978-3-947851-20-1

Traceable accounts

The chapter references enclosed in curly brackets (e.g. {2.3.1, 2.3.1.2, 2.3.1.3}) are traceable accounts and refer to sections of the chapters of the IPBES Global Assessment. A traceable account is a description within the corresponding texts of these chapters, reflecting the evaluation of the type, amount, quality, and consistency of evidence and the degree of agreement for that particular statement or key finding.

FOREWORD

A key objective of the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) is to provide Governments, the private sector and civil society with scientifically credible and independent up-to-date assessments of available knowledge for better evidence-informed policy decisions and action at the local, national, regional and global levels.

This Global Assessment of Biodiversity and Ecosystem Services has been carried out by about 150 selected experts from all regions of the world, including 16 early career fellows, assisted by 350 contributing authors. More than 15,000 scientific publications were analyzed as well as a substantive body of indigenous and local knowledge. Its chapters were accepted, and its summary for policymakers was approved, by the more than 130 Governments that constitute the Members of IPBES, at the seventh session of the IPBES Plenary (29th April to 4th May, 2019), hosted by France at UNESCO in Paris.

This report represents a critical assessment, the first in almost 15 years (since the release of the Millennium Ecosystem Assessment in 2005) and the first ever carried out by an intergovernmental body, of the status and trends of the natural world, the social implications of these trends, their direct and indirect causes, and, importantly, the actions that can still be taken to ensure a better future for all. These complex links have been assessed using a simple, yet very inclusive framework that should resonate with a wide range of stakeholders, since it recognizes diverse world views, values and knowledge systems.

The concept of nature's contributions to people, which is discussed in detail in chapter 1, embraces a wide range of descriptions of human-nature interactions, including through the concept of ecosystem services and other descriptions, which range from strongly utilitarian to strongly relational. The concept of nature's contribution to people was developed to embrace a fuller and more symmetric consideration of diverse stakeholders and world views, and a richer evidence base for action, i.e., the knowledge base offered by the natural and social sciences, the humanities, and the knowledge of practitioners and indigenous peoples and local communities. The reporting system for nature's contributions to people has a gradient of complementary and overlapping approaches, ranging from a generalizing to a context-specific perspective. The generalizing perspective is analytical in purpose and is organized into eighteen categories of material, non-material and regulating contributions. The context-specific perspective is typical of indigenous and local knowledge systems, where

IPBES is an independent intergovernmental body comprising over 130 member Governments. Established by Governments in 2012, IPBES provides policymakers with objective scientific assessments about the state of knowledge regarding the planet's biodiversity, ecosystems and the contributions they make to people, as well as options and actions to protect and sustainably use these vital natural assets.

The IPBES Global Assessment of Biodiversity and Ecosystem Services represents the landmark product of the first work programme of IPBES (2014-2018). The Global Assessment was initiated following a decision from the IPBES Plenary at its fourth session (IPBES 4, Kuala Lumpur, 2016), and considered by the IPBES Plenary at its seventh session (IPBES 7, Paris, 2019). It is composed of a summary for policymakers, which was approved at IPBES 7, and six chapters, which were accepted at IPBES 7.

knowledge production does not typically seek to explicitly extend or validate itself beyond specific geographic and cultural contexts. In this way, the nature's contributions to people approach (or the IPBES approach) builds on the existing approaches, descriptors and metrics used by different communities of practice in the search for understanding and solutions.

In the last 10-15 years, since the Millennium Ecosystem Assessment, there has been a significant increase in our understanding of biodiversity and ecosystems, as well as their importance to the quality of life of every person. There is also greater understanding now about which policies, practices, technologies and behaviors can best lead to the conservation and sustainable use of biodiversity and the achievement of many of the Sustainable Development Goals, the Aichi Biodiversity Targets and the Paris Agreement on Climate Change. However, biodiversity is still being lost, ecosystems are still being degraded and many of nature's contributions to people are being compromised.

The Assessment is critical today because evidence has accumulated that the multiple threats to biodiversity have intensified since previous reports, and that the sustainable use of nature will be vital for adapting to and mitigating dangerous anthropogenic interference with the climate system, as well as for achieving many of our most important development goals.

The findings of this Assessment focus on the global scale, spanning the period from the 1970s to 2050. They are based on an unprecedented collection of evidence, integrating natural and social science perspectives, a range of knowledge systems and multiple dimensions of value. This is the first global-level assessment to systematically consider evidence about the contributions of indigenous and local knowledge and practices, and issues concerning Indigenous Peoples and Local Communities. All these features result in a more holistic assessment of indirect drivers as root causes of changes in nature and the associated risks to the quality of life of all people.

As the Chair and the Executive Secretary of IPBES, we wish to recognize the excellent and dedicated work of the co-chairs, Professors Sandra Díaz (Argentina), Eduardo S. Brondízio (Brazil and USA), and Josef Settele (Germany) and of all the coordinating lead authors, lead authors, review editors, fellows, contributing authors and reviewers, and to warmly thank them for their commitment, and for contributing their time freely to this important report. We would also like to thank Hien Ngo and Maximilien Guèze from the technical support unit located at the IPBES secretariat in Bonn, Germany, because this report would not have been possible without their extraordinary dedication. Our thanks also go the current and former members of the Multidisciplinary Expert Panel (MEP) and of the Bureau who provided guidance as part of the management committee for this report, and to members of other technical support units within the IPBES secretariat, who have supported the production of this report. We would also like to thank all Governments and other institutions that provided financial and in-kind support for the preparation of this assessment.

The IPBES Global Assessment of Biodiversity and Ecosystem Services, together with the four IPBES regional assessments of Biodiversity and Ecosystem Services, and the two thematic Assessments of Pollination, Pollinators and Food Production, and of Land Degradation and Restoration, form an impressive corpus of knowledge to make better-informed decisions regarding the conservation and sustainable use of biodiversity. The IPBES Global Assessment is expected to be an important evidence base for the assessment of progress towards the achievement of the Aichi Biodiversity Targets in the fifth edition of the Global Biodiversity Outlook and to play a major role in the consideration of the post 2020 biodiversity framework by the 15th Conference of the Parties to the Convention on Biological Diversity, in October 2020. It is also expected to inform implementation of the 2030 Agenda for Sustainable Development, the Sustainable Development Goals and the Paris Agreement on Climate Change. It is our sincere hope that the IPBES Global Assessment will continue to place biodiversity at the top of the global political agenda, with similar priority to that accorded to climate change. The process leading to COP 15 offers this opportunity.

Sir Robert T. Watson
Chair of IPBES from 2016 to 2019

Anne Larigauderie
Executive Secretary of IPBES

STATEMENTS FROM KEY PARTNERS

Nature makes human development possible but our relentless demand for the earth's resources is accelerating extinction rates and devastating the world's ecosystems. UN Environment is proud to support the Global Assessment Report produced by the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services because it highlights the critical need to integrate biodiversity considerations in global decision-making on any sector or challenge, whether its water or agriculture, infrastructure or business.

Joyce Masuya

Acting Executive Director,
United Nations Environment Programme (UNEP)

This essential report reminds each of us of the obvious truth: the present generations have the responsibility to bequeath to future generations a planet that is not irreversibly damaged by human activity. Our local, indigenous and scientific knowledge are proving that we have solutions and so no more excuses: we must live on earth differently. UNESCO is committed to promoting respect of the living and of its diversity, ecological solidarity with other living species, and to establish new, equitable and global links of partnership and intragenerational solidarity, for the perpetuation of humankind.

Audrey Azoulay

Director-General,
United Nations Educational, Scientific and Cultural Organization (UNESCO)

The *Global assessment of biodiversity and ecosystem services* adds a major element to the body of evidence for the importance of biodiversity to efforts to achieve the Zero Hunger objective and meet the Sustainable Development Goals. Together, assessments undertaken by IPBES, FAO, CBD and other organizations point to the urgent need for action to better conserve and sustainably use biodiversity and to the importance of cross-sectoral and multidisciplinary collaboration among decision-makers and other stakeholders at all levels.

José Graziano da Silva

Director-General,
Food and Agriculture Organization of the United Nations (FAO)

Across cultures, humans inherently value nature. The magic of seeing fireflies flickering long into the night is immense. We draw energy and nutrients from nature. We find sources of food, medicine, livelihoods and innovation in nature. Our well-being fundamentally depends on nature. Our efforts to conserve biodiversity and ecosystems must be underpinned by the best science that humanity can produce. This is why the scientific evidence compiled in this IPBES Global Assessment is so important. It will help us build a stronger foundation for shaping the post 2020 global biodiversity framework: the 'New Deal for Nature and People'; and for achieving the SDGs.

Achim Steiner

Administrator,
United Nations Development Programme (UNDP)

The IPBES' 2019 Global Assessment Report on Biodiversity and Ecosystem Services comes at a critical time for the planet and all its peoples. The report's findings — and the years of diligent work by the many scientists who contributed— will offer a comprehensive view of the current conditions of global biodiversity. Healthy biodiversity is the essential infrastructure that supports all forms of life on earth, including human life. It also provides nature-based solutions on many of the most critical environmental, economic, and social challenges that we face as human society, including climate change, sustainable development, health, and water and food security. We are currently in the midst of preparing for the 2020 UN Biodiversity Conference, in China, which will mark the close of the Aichi Biodiversity Targets and set the course for a post 2020 ecologically focused sustainable development pathway to deliver multiple benefits for people, the planet and our global economy. The IPBES report will serve as a fundamental baseline of where we are and where we need to go as a global community to inspire humanity to reach the 2050 Vision of the UN Biodiversity Convention "Living in harmony with nature". I want to extend my thanks and congratulations to the IPBES community for their hard work, immense contributions and continued partnership.

Dr. Cristiana Paşca Palmer

Executive Secretary,
Convention on Biological Diversity (CBD)

ACKNOWLEDGEMENTS

The co-chairs of the IPBES Global Assessment Report of Biodiversity and Ecosystem Services wish to thank the people and institutions that helped to make the Report possible.

We are first indebted to the hundreds of experts in biophysical and social sciences, policymakers and practitioners, as well as representatives of Indigenous Peoples and Local Communities, who generously contributed their time and knowledge, as lead authors, chapter scientists, resource person, and/or review editors (listed below), and to all contributing authors. We are fortunate to have had the opportunity to work with such an engaged, collegial and superb group of authors.

We are grateful to the members of the IPBES secretariat, particularly Executive Secretary Anne Larigauderie, the IPBES Chair (Robert Watson), representatives of member States, the Multidisciplinary Expert Panel and Bureau and other resource persons for their dedication, strategic vision, constructive comments and continued advice. The Global Assessment would not have been possible without the titanic effort of its technical support unit (Hien T. Ngo and Maximilien Guèze) during the whole process, including the long and challenging seventh session of the IPBES Plenary (#IPBES7), which resulted in the approval of this report and its summary for policymakers. In addition, we are thankful for the support of several IPBES technical support units, and their host institutions at different stages of the process: Knowledge and data technical support unit (NIE, Republic of Korea), indigenous and local knowledge technical support unit (UNESCO), scenarios and models technical support unit (PBL, Netherlands), and the capacity building technical support unit (NEA, Norway). We also thank the data visualization specialist and the graphic designer for their skillful work. We would like to thank the IPBES communications team, for their outstanding work communicating the main messages to the general public.

We are also grateful to all supportive Governments but in particular the Governments of Germany, South Africa, Norway, the United Kingdom, France, and the Netherlands as well as to the Córdoba Province (Argentina), who generously hosted our chapter and/or author meetings. The co-chairs would especially like to acknowledge the support of their home institutions and governments: the Helmholtz Centre for Environmental Research – UFZ (Germany), iDiv (the German Centre for Integrative Biodiversity Research), Universidad Nacional de Córdoba and CONICET (Argentina), and Indiana University-Bloomington (USA). Finally, our gratitude goes to the Government of France for hosting #IPBES 7 and to UNESCO for providing the venue and support. The dedication and contributions of all of the governments, organizations and people above made the Global Assessment possible and impactful and for that we are deeply indebted and appreciative.

Eduardo S. Brondízio, Josef Settele, Sandra Díaz
Co-Chairs

We are grateful to the following lead authors, fellows and chapter scientists of the IPBES Global Assessment:
C. Adams, J. Agard, A. P. D. Aguiar, D. Armenteras, A. Arneth, Y. Aumeeruddy-Thomas, X. Bai, P. Balvanera, T. Bekele Gode, E. Bennett, Y. A. Boafo, A. K. Boedhihartono, P. Brancalion, K. Brauman, E. R. T. Watson, I. A. Baste, A. Larigauderie, P. Leadley, U. Pascual, D. Cooper, B. Baptiste, S. Demissew, L. Dziba, G. Erpul, A. Fazel, M. Fischer, A. M. Hernández, M. Karki, V. Mathur, T. Pataridze, I. Sousa Pinto, M. Stenseke, K. Török and B. Vilá.

This IPBES Global Assessment of Biodiversity and Ecosystem Services is dedicated to the memory of Georgina Mace.

Georgina was a Fellow of the Royal Society and received during her rich career an impressive list of honors and prizes worldwide. She strongly believed in the power of science to inform policymaking and, following her involvement in the Millennium Ecosystem Assessment, played, as Chair of the Scientific Committee of DIVERSITAS, a key role in supporting the process that led in 2012 to the establishment of IPBES.

Georgina followed the work of IPBES very closely and, for this IPBES Global Assessment, played the critical role of overall review editor. She will be greatly missed and remembered for her lifelong commitment to biodiversity, to science and to science-policy, for being a loyal friend to so many, and for her vision, style, leadership, modesty and sense of humour.

The global assessment report on BIODIVERSITY AND ECOSYSTEM SERVICES

SUMMARY FOR POLICYMAKERS

KEY MESSAGES

KEY MESSAGES

A. Nature and its vital contributions to people, which together embody biodiversity and ecosystem functions and services, are deteriorating worldwide.

Nature embodies different concepts for different people, including biodiversity, ecosystems, Mother Earth, systems of life and other analogous concepts. Nature's contributions to people embody different concepts, such as ecosystem goods and services and nature's gifts. Both nature and nature's contributions to people are vital for human existence and good quality of life (human well-being, living in harmony with nature, living well in balance and harmony with Mother Earth, and other analogous concepts). While more food, energy and materials than ever before are now being supplied to people in most places, this is increasingly at the expense of nature's ability to provide such contributions in the future, and frequently undermines nature's many other contributions, which range from water quality regulation to sense of place. The biosphere, upon which humanity as a whole depends, is being altered to an unparalleled degree across all spatial scales. Biodiversity – the diversity within species, between species and of ecosystems – is declining faster than at any time in human history.

A1 Nature is essential for human existence and good quality of life. Most of nature's contributions to people are not fully replaceable, and some are irreplaceable. Nature plays a critical role in providing food and feed, energy, medicines and genetic resources and a variety of materials fundamental for people's physical well-being and for maintaining culture. For example, more than 2 billion people rely on wood fuel to meet their primary energy needs, an estimated 4 billion people rely primarily on natural medicines for their health care and some 70 per cent of drugs used for cancer are natural or are synthetic products inspired by nature. Nature, through its ecological and evolutionary processes, sustains the quality of the air, fresh water and soils on which humanity depends, distributes fresh water, regulates the climate, provides pollination and pest control and reduces the impact of natural hazards. For example, more than 75 per cent of global food crop types, including fruits and vegetables and some of the most important cash crops, such as coffee, cocoa and almonds, rely on animal pollination. Marine and terrestrial ecosystems are the sole sinks for anthropogenic carbon emissions, with a gross sequestration of 5.6 gigatons of carbon per year (the equivalent of some 60 per cent of global anthropogenic emissions). Nature underpins all dimensions of human health and contributes to non-material aspects of quality of life – inspiration and learning, physical and psychological experiences, and supporting identities – that are central to quality of life and cultural integrity, even if their aggregated value is difficult to quantify. Most of nature's contributions are co-produced with people, but while anthropogenic assets – knowledge and institutions, technology infrastructure and financial capital – can enhance or partially replace some of those contributions, some are irreplaceable. The diversity of nature maintains humanity's ability to choose alternatives in the face of an uncertain future.

A2 Nature's contributions to people are often distributed unequally across space and time and among different segments of society. There are often trade-offs in the production and use of nature's contributions. Benefits and burdens associated with co-production and use of nature's contributions are distributed and experienced differently among social groups, countries and regions. Giving priority to one of nature's contributions to people, such as food production, can result in ecological changes that reduce other contributions. Some of these changes may benefit some people at the expense of others, particularly the most vulnerable, as may changes in technological and institutional arrangements. For example, although food production today is sufficient to satisfy global needs, approximately 11 per cent of the world's population is undernourished, and diet-related disease drives 20 per cent of premature mortality, related both to undernourishment and to obesity. The great expansion in the production of food, feed, fibre and bioenergy has occurred at the cost of many other contributions of nature to quality of life, including regulation of air and water quality, climate regulation and habitat provision. Synergies also exist, such as sustainable agricultural practices that enhance soil quality, thereby improving productivity and other ecosystem functions and services, such as carbon sequestration and water quality regulation.

A3 Since 1970, trends in agricultural production, fish harvest, bioenergy production and harvest of materials have increased, but 14 of the 18 categories of contributions of nature that were assessed, mostly regulating and non-material contributions, have declined. The value of agricultural crop production ($2.6 trillion in 2016) has increased approximately threefold since 1970 and raw timber harvest has increased by 45 per cent, reaching some 4 billion cubic metres in 2017, with the forestry industry providing about 13.2 million jobs. However, indicators of regulating contributions, such as soil organic carbon and pollinator diversity, have declined, indicating that gains in material contributions are often not sustainable. Currently, land degradation has reduced productivity in 23 per cent of the global terrestrial area, and between $235 billion and $577 billion[3] in annual global crop output is at risk as a result of pollinator loss. Moreover, loss of coastal habitats and coral reefs reduces coastal protection, which increases the risk from floods and hurricanes to life and property for the 100 million to 300 million people living within coastal 100-year flood zones.

A4 Nature across most of the globe has now been significantly altered by multiple human drivers, with the great majority of indicators of ecosystems and biodiversity showing rapid decline. Seventy-five per cent of the land surface is significantly altered, 66 per cent of the ocean area is experiencing increasing cumulative impacts, and over 85 per cent of wetlands (area) has been lost. While the rate of forest loss has slowed globally since 2000, this is distributed unequally. Across much of the highly biodiverse tropics, 32 million hectares of primary or recovering forest were lost between 2010 and 2015. The extent of tropical and subtropical forests is increasing within some countries, and the global extent of temperate and boreal forests is increasing. A range of actions – from restoration of natural forest to planting of monocultures – contributes to these increases, but these actions have very different consequences for biodiversity and its contributions to people. Approximately half the live coral cover on coral reefs has been lost since the 1870s, with accelerating losses in recent decades due to climate change exacerbating other drivers. The average abundance of native species in most major terrestrial biomes has fallen by at least 20 per cent, potentially affecting ecosystem processes and hence nature's contributions to people; this decline has mostly taken place since 1900 and may be accelerating. In areas of high endemism, native biodiversity has often been severely impacted by invasive alien species. Population sizes of wild vertebrate species have tended to decline over the last 50 years on land, in freshwater and in the sea. Global trends in insect populations are not known but rapid declines have been well documented in some places.

A5 Human actions threaten more species with global extinction now than ever before. An average of around 25 per cent of species in assessed animal and plant

3. Value adjusted to 2015 United States dollars, taking into account inflation only.

groups are threatened **(Figure SPM.3)**, suggesting that around 1 million species already face extinction, many within decades, unless action is taken to reduce the intensity of drivers of biodiversity loss. Without such action, there will be a further acceleration in the global rate of species extinction, which is already at least tens to hundreds of times higher than it has averaged over the past 10 million years **(Figure SPM.4)**.

A6 Globally, local varieties and breeds of domesticated plants and animals are disappearing. This loss of diversity, including genetic diversity, poses a serious risk to global food security by undermining the resilience of many agricultural systems to threats such as pests, pathogens and climate change. Fewer and fewer varieties and breeds of plants and animals are being cultivated, raised, traded and maintained around the world, despite many local efforts, which include those by indigenous peoples and local communities. By 2016, 559 of the 6,190 domesticated breeds of mammals used for food and agriculture (over 9 per cent) had become extinct and at least 1,000 more are threatened. In addition, many crop wild relatives that are important for long-term food security lack effective protection, and the conservation status of wild relatives of domesticated mammals and birds is worsening. Reductions in the diversity of cultivated crops, crop wild relatives and domesticated breeds mean that agroecosystems are less resilient against future climate change, pests and pathogens.

A7 Biological communities are becoming more similar to each other in both managed and unmanaged systems within and across regions. This human-caused process leads to losses of local biodiversity, including endemic species, ecosystem functions and nature's contributions to people.

A8 Human-induced changes are creating conditions for fast biological evolution – so rapid that its effects can be seen in only a few years or even more quickly. The consequences can be positive or negative for biodiversity and ecosystems, but can create uncertainty about the sustainability of species, ecosystem functions and the delivery of nature's contributions to people. Understanding and monitoring these biological evolutionary changes is as important for informed policy decisions as it is in cases of ecological change. Sustainable management strategies then can be designed to influence evolutionary trajectories so as to protect vulnerable species and reduce the impact of unwanted species (such as weeds, pests or pathogens). The widespread declines in geographic distribution and population sizes of many species make clear that, although evolutionary adaptation to human-caused drivers can be rapid, it has often not been sufficient to mitigate them fully.

B. Direct and indirect drivers of change have accelerated during the past 50 years.

The rate of global change in nature during the past 50 years is unprecedented in human history. The direct drivers of change in nature with the largest global impact have been (starting with those with most impact): changes in land and sea use; direct exploitation of organisms; climate change; pollution; and invasion of alien species. Those five direct drivers result from an array of underlying causes – the indirect drivers of change – which are in turn underpinned by societal values and behaviours that include production and consumption patterns, human population dynamics and trends, trade, technological innovations and local through global governance. The rate of change in the direct and indirect drivers differs among regions and countries.

B1 For terrestrial and freshwater ecosystems, land-use change has had the largest relative negative impact on nature since 1970, followed by the direct exploitation, in particular overexploitation, of animals, plants and other organisms, mainly via harvesting, logging, hunting and fishing. In marine ecosystems, direct exploitation of organisms (mainly fishing) has had the largest relative impact, followed by land-/sea-use change. Agricultural expansion is the most widespread form of land-use change, with over one third of the terrestrial land surface being used for cropping or animal husbandry. This expansion, alongside a doubling of urban area since 1992 and an unprecedented expansion of infrastructure linked to growing population and consumption, has come mostly at the expense of forests (largely old-growth tropical forests), wetlands and grasslands. In freshwater ecosystems, a series of combined threats that include land-use change, including water extraction, exploitation, pollution, climate change and invasive species, are prevalent. Human activities have had a large and widespread impact on the world's oceans. These include direct exploitation, in particular overexploitation, of fish, shellfish and other organisms, land- and sea-based pollution, including from river networks, and land-/sea-use change, including coastal development for infrastructure and aquaculture.

B2 Climate change is a direct driver that is increasingly exacerbating the impact of other drivers on nature and human well-being. Humans are estimated to have caused an observed warming of approximately 1.0°C by 2017 relative to pre-industrial levels, with average temperatures over the past 30 years rising by 0.2°C per decade. The frequency and intensity of extreme weather events, and the fires, floods and droughts that they can bring, have increased in the past 50 years, while the global average sea level has risen by between 16 and 21 cm since 1900, and at a rate of more than 3 mm per year over the past two decades. These changes have contributed to widespread impacts in many aspects of biodiversity, including species distribution, phenology, population dynamics, community structure and ecosystem function. According to observational evidence, the effects are accelerating in marine, terrestrial and freshwater ecosystems and are already impacting agriculture, aquaculture, fisheries and nature's contributions to people. The compounding effects of drivers such as climate change, land-/sea-use change, overexploitation of resources, pollution and invasive alien species are likely to exacerbate the negative impacts on nature, as seen in different ecosystems including coral reefs, the Arctic systems and savannas.

B3 Many types of pollution, as well as invasive alien species, are increasing, with negative impacts for nature. Although global trends are mixed, air, water and soil pollution have continued to increase in some areas. Marine plastic pollution in particular has increased tenfold since 1980, affecting at least 267 species, including 86 per cent of marine turtles, 44 per cent of seabirds and 43 per cent of marine mammals. This can affect humans through food chains. Greenhouse gas emissions, untreated urban and rural waste, pollutants from industrial, mining and agricultural activities, oil spills and toxic dumping have had strong negative effects on soil, freshwater and marine water quality and on the global atmosphere. Cumulative records of alien species have increased by 40 per cent since 1980, associated with increased trade and human population dynamics and trends. Nearly one fifth of the Earth's surface is at risk of plant and animal invasions, impacting native species, ecosystem functions and nature's contributions to people, as well as economies and human health. The rate of introduction of new invasive alien species seems higher than ever before and shows no signs of slowing.

B4 In the past 50 years, the human population has doubled, the global economy has grown nearly fourfold and global trade has grown tenfold, together driving up the demand for energy and materials. A variety of economic, political and social factors, including global trade and the spatial decoupling of production from consumption, have shifted the economic and environmental gains and losses of production and consumption, contributing to new economic opportunities, but also to impacts on nature and its contributions to people. Levels of consumption of material goods (food, feed, timber and fibre) vary greatly, and unequal access to material goods can be associated with inequity and may lead to social conflict. Economic exchange contributes to aggregate economic development, yet often is negotiated between actors and institutions of unequal power, which influences the distribution of benefits and long-term impacts. Countries at different levels of development have experienced different levels of deterioration of nature for any given gain in economic growth. Exclusion, scarcity and/or the unequal distribution of nature's contributions to people may fuel social instability and conflict in a complex interaction with other factors. Armed conflicts have an impact on ecosystems beyond their destabilizing effects on societies, and a range of indirect impacts, including the displacement of people and activities.

B5 Economic incentives have generally favoured expanding economic activity, and often environmental harm, over conservation or restoration. Incorporating the consideration of the multiple values of ecosystem functions and of nature's contributions to people into economic incentives has, in the economy, been shown to permit better ecological, economic and social outcomes. Local, national, regional and global governance initiatives have improved outcomes in this way by supporting policies, innovation and the elimination of environmentally harmful subsidies, introducing incentives in line with the value of nature's contribution to people, increasing sustainable land-/sea-use management and enforcing regulations, among other measures. Harmful economic incentives and policies associated with unsustainable practices in fisheries, aquaculture, agriculture (including fertilizer and pesticide use), livestock management, forestry, mining and energy (including fossil fuels and biofuels) are often associated with land-/sea-use change and overexploitation of natural resources, as well as inefficient production and waste management. Vested interests may oppose the removal of subsidies or the introduction of other policies. Yet policy reforms to deal with such causes of environmental harm offer the potential to both conserve nature and provide economic benefits, including when policies are based on more and better understanding of the multiple values of nature's contributions.

B6 Nature managed by indigenous peoples and local communities is under increasing pressure. Nature is generally declining less rapidly in indigenous peoples' land than in other lands, but is nevertheless declining, as is the knowledge of how to manage it. At least a quarter of the global land area is traditionally owned, managed[4], used or occupied by indigenous peoples. These areas include approximately 35 per cent of the area that is formally protected, and approximately 35 per cent of all remaining terrestrial areas with very low human intervention. In addition, a diverse array of local communities, including farmers, fishers, herders, hunters, ranchers and forest users, manage significant areas under various property and access regimes. Among the local indicators developed and used by indigenous peoples and local communities, 72 per cent show negative trends in nature that underpin local livelihoods and well-being. The areas managed (under various types of tenure and access regimes) by indigenous peoples and local communities are facing growing resource extraction, commodity production, mining and transport and energy infrastructure, with various consequences for local livelihoods and health. Some climate change mitigation programmes have had negative impacts on indigenous peoples and local communities. The negative impacts of all these pressures include continued loss of subsistence and traditional livelihoods resulting from ongoing deforestation, loss of wetlands, mining, the spread of unsustainable agriculture, forestry and fishing practices and impacts on health and well-being from pollution and water insecurity. These impacts also challenge traditional management, the transmission of indigenous and local knowledge, the potential for sharing of benefits arising from the use of, and the ability of indigenous peoples and local communities to conserve and sustainably manage, wild and domesticated biodiversity that are also relevant to broader society.

C. Goals for conserving and sustainably using nature and achieving sustainability cannot be met by current trajectories, and goals for 2030 and beyond may only be achieved through transformative changes[5] across economic, social, political and technological factors.

Past and ongoing rapid declines in biodiversity, ecosystem functions and many of nature's contributions to people mean that most international societal and environmental goals, such as those embodied in the Aichi Biodiversity Targets and the 2030 Agenda for Sustainable Development, will not be achieved based on current trajectories. These declines will also undermine other goals, such as those specified in the Paris Agreement adopted under the United Nations Framework Convention on Climate Change and the 2050 Vision for Biodiversity.

4. These data sources define land management here as the process of determining the use, development and care of land resources in a manner that fulfils material and non-material cultural needs, including livelihood activities such as hunting, fishing, gathering, resource harvesting, pastoralism and small-scale agriculture and horticulture.

5. A fundamental, system-wide reorganization across technological, economic and social factors, including paradigms, goals and values.

The negative trends in biodiversity and ecosystem functions are projected to continue or worsen in many future scenarios in response to indirect drivers such as rapid human population growth, unsustainable production and consumption and associated technological development. In contrast, scenarios and pathways that explore the effects of low-to-moderate population growth, and transformative changes in the production and consumption of energy, food, feed, fibre and water, sustainable use, equitable sharing of the benefits arising from use and nature-friendly climate adaptation and mitigation will better support the achievement of future societal and environmental objectives.

C1 **The implementation of policy responses and actions to conserve nature and manage it more sustainably has progressed, yielding positive outcomes relative to scenarios of no intervention, but progress is not sufficient to stem the direct and indirect drivers of nature deterioration. It is therefore likely that most of the Aichi Biodiversity Targets for 2020 will be missed.** Some of the Aichi Biodiversity Targets will be partially achieved, for example those related to policy responses, such as the spatial extent of terrestrial and marine protected areas, the identification and prioritization of invasive alien species, national biodiversity strategies and action plans, and the Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization to the Convention on Biological Diversity. However, while protected areas now cover 15 per cent of terrestrial and freshwater environments and 7 per cent of the marine realm, they only partly cover important sites for biodiversity and are not yet fully ecologically representative and effectively or equitably managed. There has been significant growth in official development assistance in support of the Convention on Biological Diversity and in funding provided by the Global Environment Facility, with biodiversity aid flows reaching $8.7 billion annually. However, current resource mobilization from all sources is not sufficient to achieve the Aichi Biodiversity Targets. In addition, only one in five of the strategic objective and goals across six global agreements[6] relating to nature and the protection of the global environment are demonstrably on track to be met. For nearly one third of the goals of these conventions, there has been little or no progress towards them or, instead, movement away from them.

C2 **Nature is essential for achieving the Sustainable Development Goals. However, taking into consideration that the Sustainable Development Goals are integrated, indivisible, and nationally implemented, current negative trends in biodiversity and ecosystems will undermine progress towards 80 per cent (35 out of 44) of the assessed targets of Goals related to poverty, hunger, health, water, cities, climate, oceans and land (Sustainable Development Goals 1, 2, 3, 6, 11, 13, 14, and 15).** Important positive synergies between nature and the Goals related to education, gender equality, reducing inequalities and promoting peace and justice (Sustainable Development Goals 4, 5, 10 and 16) were found. Land or resource tenure insecurity, as well as declines in nature, have greater impacts on women and girls, who are most often negatively impacted. However, the current focus and wording of the targets of these Goals obscures or omits their relationship to nature, thereby preventing their assessment here. There is a critical need for future policy targets, indicators and datasets to more explicitly account for aspects of nature and their relevance to human well-being in order to more effectively track the consequences of trends in nature on the Sustainable Development Goals. Some pathways chosen to achieve the Goals related to energy, economic growth, industry and infrastructure, and sustainable consumption and production (Sustainable Development Goals 7, 8, 9 and 12), as well as the targets related to poverty, food security and cities (Sustainable Development Goals 1, 2 and 11), could have substantial positive or negative impacts on nature and therefore on the achievement of the other Sustainable Development Goals.

C3 **Areas of the world projected to experience significant negative effects from global changes in climate, biodiversity, ecosystem functions and nature's contributions to people are also home to large concentrations of indigenous peoples and many of the world's poorest communities.** Because of their strong dependency on nature and its contributions for subsistence, livelihoods and health, those communities will be disproportionately hard-hit by those negative changes. Those negative effects also influence the ability of indigenous peoples and local communities to manage and conserve wild and domesticated biodiversity and nature's contributions to people. Indigenous peoples and local communities have been proactively confronting such challenges in partnership with each other and with an array of other stakeholders, through co-management systems

6. Convention on the Conservation of Migratory Species of Wild Animals, Convention on International Trade in Endangered Species of Wild Fauna and Flora, Convention concerning the Protection of the World Cultural and Natural Heritage, International Plant Protection Convention, United Nations Convention to Combat Desertification in Those Countries Experiencing Serious Drought and/or Desertification, Particularly in Africa, and Convention on Wetlands of International Importance especially as Waterfowl Habitat.

and local and regional monitoring networks and by revitalizing and adapting local management systems. Regional and global scenarios lack an explicit consideration of the views, perspectives and rights of indigenous peoples and local communities, their knowledge and understanding of large regions and ecosystems, and their desired future development pathways.

C4 **Except in scenarios that include transformative change, negative trends in nature, in ecosystem functions and in many of nature's contributions to people are projected to continue to 2050 and beyond, due to the projected impacts of increasing land-/and sea-use change, exploitation of organisms and climate change.** Negative impacts arising from pollution and invasive alien species will likely exacerbate these trends. There are large regional differences in the projected patterns of future biodiversity and ecosystem functions and in the losses and changes in nature's contributions to people. These differences arise from the direct and indirect drivers of change, which are projected to impact regions in different ways. While regions worldwide face further declines in biodiversity in future projections, tropical regions face particular combined risks of declines due to the interactions between climate change, land-use change and fisheries exploitation. Marine and terrestrial biodiversity in boreal, subpolar and polar regions is projected to decline mostly because of warming, sea ice retreat and enhanced ocean acidification. The magnitude of the impacts and the differences between regions are much greater in scenarios with rapid increases in consumption or human population than in scenarios based on sustainability. Acting immediately and simultaneously on the multiple indirect and direct drivers has the potential to slow, halt and even reverse some aspects of biodiversity and ecosystem loss.

C5 **Climate change is projected to become increasingly important as a direct driver of changes in nature and its contributions to people in the next decades. Scenarios show that meeting the Sustainable Development Goals and the 2050 Vision for Biodiversity depends on taking into account climate change impacts in the definition of future goals and objectives.** The future impacts of climate change are projected to become more pronounced in the next decades, with variable relative effects depending on scenario and geographic region. Scenarios project mostly adverse climate change effects on biodiversity and ecosystem functioning, which worsen, in some cases exponentially, with incremental global warming. Even for global warming of 1.5°C to 2°C, the majority of terrestrial species ranges are projected to shrink dramatically. Changes in ranges can adversely affect the capacity of terrestrial protected areas to conserve species, greatly increase local species turnover and substantially increase the risk of global extinctions. For example, a synthesis of many studies estimates that the fraction of species at risk of climate-related extinction is 5 per cent at 2°C warming and rises to 16 per cent at 4.3°C warming. Coral reefs are particularly vulnerable to climate change and are projected to decline to 10 to 30 per cent of former cover at 1.5°C warming and to less than 1 per cent of former cover at 2°C warming. Therefore, scenarios show that limiting global warming to well below 2°C plays a critical role in reducing adverse impacts on nature and its contributions to people.

D. Nature can be conserved, restored and used sustainably while other global societal goals are simultaneously met through urgent and concerted efforts fostering transformative change.

Societal goals, including those related to food, water, energy, health and the achievement of human well-being for all, mitigating and adapting to climate change and conserving and sustainably using nature, can be achieved in sustainable pathways through the rapid and improved deployment of existing policy instruments and new initiatives that more effectively enlist individual and collective action for transformative change. Since current structures often inhibit sustainable development and actually represent the indirect drivers of biodiversity loss, such fundamental, structural change is called for. By its very nature, transformative change can expect opposition from those with interests vested in the status quo, but such opposition can be overcome for the broader public good. If obstacles are overcome, a commitment to mutually supportive international goals and targets, supporting actions by indigenous peoples and local communities at the local level, new frameworks for private sector investment and innovation, inclusive and adaptive governance approaches and arrangements, multi-sectoral planning, and strategic policy mixes can help to transform the public and private sectors to achieve sustainability at the local, national and global levels.

D1 **The global environment can be safeguarded through enhanced international cooperation and linked, locally relevant measures. The review and renewal of internationally agreed environment-related goals and targets, based on the best available scientific knowledge and the widespread adoption and funding of action on conservation, ecological restoration and sustainable use by all actors, including individuals, are key to this safeguarding.** Such widespread adoption implies advancing and aligning local, national and international sustainability efforts and mainstreaming biodiversity and sustainability across all extractive and productive sectors, including mining, fisheries, forestry and agriculture, so that together, individual and collective actions result in a reversal of the deterioration of ecosystem services at the global level. Yet these bold changes to the direct drivers of the deterioration of nature cannot be achieved without transformative change that simultaneously addresses the indirect drivers.

D2 **Five main interventions ("levers") can generate transformative change by tackling the underlying indirect drivers of the deterioration of nature: (1) incentives and capacity-building; (2) cross-sectoral cooperation; (3) pre-emptive action; (4) decision-making in the context of resilience and uncertainty; and (5) environmental law and implementation.** Using these levers will involve the following: (1) developing incentives and widespread capacity for environmental responsibility and eliminating perverse incentives; (2) reforming sectoral and segmented decision-making to promote integration across sectors and jurisdictions; (3) taking pre-emptive and precautionary actions in regulatory and management institutions and businesses to avoid, mitigate and remedy the deterioration of nature, and monitoring their outcomes; (4) managing for resilient social and ecological systems in the face of uncertainty and complexity, to deliver decisions that are robust in a wide range of scenarios; and (5) strengthening environmental laws and policies and their implementation, and the rule of law more generally. All five levers may require new resources, particularly in low-capacity contexts, such as in many developing countries.

D3 **Transformations towards sustainability are more likely when efforts are directed at the following key leverage points, where efforts yield exceptionally large effects (Figure SPM.9): (1) visions of a good life; (2) total consumption and waste; (3) values and action; (4) inequalities; (5) justice and inclusion in conservation; (6) externalities and telecouplings; (7) technology, innovation and investment; and (8) education and knowledge generation and sharing.** Specifically, the following changes are mutually reinforcing: (1) enabling visions of a good quality of life that do not entail ever-increasing material consumption; (2) lowering total consumption and waste, including by addressing both population growth and per capita consumption differently in different contexts; (3) unleashing existing, widely-held values of responsibility to effect new social norms for sustainability, especially by extending notions of responsibility to include the impacts associated with consumption; (4) addressing inequalities, especially regarding income and gender, which undermine the capacity for sustainability; (5) ensuring inclusive decision-making and the fair and equitable sharing of benefits arising from the use of and adherence to human rights in conservation decisions; (6) accounting for nature deterioration from local economic activities and socioeconomic and environmental interactions over distances (telecouplings), including, for example, international trade; (7) ensuring environmentally friendly technological and social innovation, taking into account potential rebound effects and investment regimes; and (8) promoting education, knowledge generation and the maintenance of different knowledge systems, including in the sciences and indigenous and local knowledge, regarding nature, conservation and its sustainable use.

D4 **The character and trajectories of transformation will vary across contexts, with challenges and needs differing, among others, in developing and developed countries. Risks related to the inevitable uncertainties and complexities in transformations towards sustainability can be reduced through governance approaches that are integrative, inclusive, informed and adaptive.** Such approaches typically take into account the synergies and trade-offs between societal goals and alternative pathways and recognize a plurality of values, diverse economic conditions, inequity, power imbalances and vested interests in society. Risk-reducing strategies typically include learning from experience that is based on a combination of precautionary measures and existing and emerging knowledge. These approaches involve stakeholders in the coordination of policies across sectors and in the creation of strategic, locally relevant mixes of successful policy instruments. The private sector can play a role in partnership with other actors, including national and subnational governments and civil society; for example, public-private partnerships in the water sector have been an important vehicle for financing investments to meet the Sustainable Development Goals. Some effective policy measures include the expansion and strengthening of ecologically representative, well-connected protected-area networks and of other effective area-based conservation measures; the protection of watersheds; and incentives and sanctions to reduce pollution **(Table SPM.1)**.

D5 Recognizing the knowledge, innovations, practices, institutions and values of indigenous peoples and local communities, and ensuring their inclusion and participation in environmental governance, often enhances their quality of life and the conservation, restoration and sustainable use of nature, which is relevant to broader society. Governance, including customary institutions and management systems and co-management regimes that involve indigenous peoples and local communities, can be an effective way to safeguard nature and its contributions to people by incorporating locally attuned management systems and indigenous and local knowledge. The positive contributions of indigenous peoples and local communities to sustainability can be facilitated through national recognition of land tenure, access and resource rights in accordance with national legislation, the application of free, prior and informed consent, and improved collaboration, fair and equitable sharing of benefits arising from the use, and co-management arrangements with local communities.

D6 Feeding humanity and enhancing the conservation and sustainable use of nature are complementary and closely interdependent goals that can be advanced through sustainable agriculture, aquaculture and livestock systems, the safeguarding of native species, varieties, breeds and habitats, and ecological restoration. Specific actions include promoting sustainable agricultural and agroecological practices, such as multifunctional landscape planning and cross-sectoral integrated management, that support the conservation of genetic diversity and the associated agricultural biodiversity. Further actions to simultaneously achieve food security, biodiversity protection and sustainable use are context appropriate climate change mitigation and adaptation; incorporating knowledge from various systems, including the sciences and sustainable indigenous and local practices; avoiding food waste; empowering producers and consumers to transform supply chains; and facilitating sustainable and healthy dietary choices. As part of integrated landscape planning and management, prompt ecological restoration, emphasizing the use of native species, can offset the current degradation and save many endangered species, but is less effective if delayed.

D7 Sustaining and conserving fisheries and marine species and ecosystems can be achieved through a coordinated mix of interventions on land, in freshwater and in the oceans, including multilevel coordination across stakeholders on the use of open oceans. Specific actions could include, for example, ecosystem-based approaches to fisheries management, spatial planning, effective quotas, marine protected areas, protecting and managing key marine biodiversity areas, reducing run-off pollution into oceans and working closely with producers and consumers **(Table SPM.1)**. It is important to enhance capacity-building for the adoption of best fisheries management practices; adopt measures to promote conservation financing and corporate social responsibility; develop new legal and binding instruments; implement and enforce global agreements for responsible fisheries; and urgently take all steps necessary to prevent, deter and eliminate illegal, unreported and unregulated fishing.

D8 Land-based climate change mitigation activities can be effective and support conservation goals (Table SPM.1). However, the large-scale deployment of bioenergy plantations and afforestation of non-forest ecosystems can come with negative side effects for biodiversity and ecosystem functions. Nature-based solutions with safeguards are estimated to provide 37 per cent of climate change mitigation until 2030 needed to meet the goal of keeping climate warming below 2°C, with likely co-benefits for biodiversity. Therefore, land-use actions are indispensable, in addition to strong actions to reduce greenhouse gas emissions from fossil fuel use and other industrial and agricultural activities. However, the large-scale deployment of intensive bioenergy plantations, including monocultures, replacing natural forests and subsistence farmlands, will likely have negative impacts on biodiversity and can threaten food and water security as well as local livelihoods, including by intensifying social conflict.

D9 Nature-based solutions can be cost-effective for meeting the Sustainable Development Goals in cities, which are crucial for global sustainability. Increased use of green infrastructure and other ecosystem-based approaches can help to advance sustainable urban development while reinforcing climate mitigation and adaptation. Urban key biodiversity areas should be safeguarded. Solutions can include retrofitting green and blue infrastructure, such as creating and maintaining green spaces and biodiversity-friendly water bodies, urban agriculture, rooftop gardens and expanded and accessible vegetation cover in existing urban and peri-urban areas and new developments. Green infrastructure in urban and surrounding rural areas can complement large-scale "grey infrastructure" in areas such as flood protection, temperature regulation, cleaning of air and water, treating wastewater and the provision of energy, locally sourced food and the health benefits of interaction with nature.

D10 A key component of sustainable pathways is the evolution of global financial and economic

systems to build a global sustainable economy, steering away from the current, limited paradigm of economic growth. That implies incorporating the reduction of inequalities into development pathways, reducing overconsumption and waste and addressing environmental impacts, such as externalities of economic activities, from the local to the global scales. Such an evolution could be enabled through a mix of policies and tools (such as incentive programmes, certification and performance standards) and through more internationally consistent taxation, supported by multilateral agreements and enhanced environmental monitoring and evaluation. It would also entail a shift beyond standard economic indicators such as gross domestic product to include those able to capture more holistic, long-term views of economics and quality of life.

BACK-GROUND

BACKGROUND

A. Nature and its vital contributions to people, which together embody biodiversity and ecosystem functions and services, are deteriorating worldwide.

1 **Nature underpins quality of life by providing basic life support for humanity (regulating), as well as material goods (material) and spiritual inspiration (non-material) *(well established)* {2.3.1, 2.3.2}. Most of nature's contributions to people (NCP) are co-produced by biophysical processes and ecological interactions with anthropogenic assets such as knowledge, infrastructure, financial capital, technology and the institutions that mediate them *(well established)* {2.3.2} (Appendix I)**. For example, marine and freshwater-based food is co-produced by the combination of fish populations, fishing gear, and access to fishing grounds {2.3.3} There is unequal access to nature's contributions and unequal impact of nature's contributions on different social groups *(established but incomplete)* {2.3.5}. Furthermore, increases in the production of some of nature's contributions cause declines in others **(Figure SPM.1)** {2.3.2, 2.3.5}, which also affects people differently *(well established)*. For example, clearing of forest for agriculture has increased the supply of food, feed, (NCP 12) and other materials important for people (such as natural fibres and ornamental flowers: NCP 13), but has reduced contributions as diverse as pollination (NCP 2), climate regulation (NCP 4), water quality regulation (NCP 7), opportunities for learning and inspiration (NCP 15) and the maintenance of options for the future (NCP 18). However, very few large-scale systematic studies exist on those relationships {2.3.2}. Land degradation has reduced productivity in 23 per cent of the global terrestrial area, and between $235 billion and $577 billion in annual global crop output is at risk as a result of pollinator loss {2.3.5.3} *(established but incomplete).*

2 **Many of nature's contributions to people are essential for human health (*well established*) and their decline thus threatens a good quality of life (*established but incomplete*) {2.3.4}.** Nature provides a broad diversity of nutritious foods, medicines and clean water *(well established)* {2.3.5.2, 3.3.2.1, 3.3.2.2 (Sustainable Development Goal 3)}; can help to regulate disease and the immune system {2.3.4.2}; can reduce levels of certain air pollutants *(established but incomplete)* {2.3.4.2, 3.3.2.2}; and can improve mental and physical health through exposure to natural areas *(inconclusive)*, among other contributions {2.3.2.2, 2.3.4.2, 3.3.2.2 (Sustainable Development Goal 3)}. Nature is the origin of most infectious diseases (negative impact), but also the source of medicines and antibiotics for treatment (positive contribution) *(well established)*. Zoonotic diseases are significant threats to human health, with vector-borne diseases accounting for approximately 17 per cent of all infectious diseases and causing an estimated 700,000 deaths globally per annum *(established but incomplete)* {3.3.2.2}. Emerging infectious diseases in wildlife, domestic animals, plants or people can be exacerbated by human activities such as land clearing and habitat fragmentation *(established but incomplete)* or the overuse of antibiotics driving rapid evolution of antibiotic resistance in many bacterial pathogens *(well established)* {3.3.2.2}. The deterioration of nature and consequent disruption of benefits to people has both direct and indirect implications for public health *(well established)* {2.3.5.2} and can exacerbate existing inequalities in access to health care or healthy diets *(established but incomplete)* {2.3.4.2}. Shifting diets towards a diversity of foods, including fish, fruit, nuts and vegetables, significantly reduces the risk of certain preventable non-communicable diseases, which are currently responsible for 20 per cent of premature mortality globally *(well established)* {2.3.4.2, 2.3.5.2 (NCP 2 and 12)}.

3 **Most of nature's contributions are not fully replaceable, yet some contributions of nature are irreplaceable (*well established*).** Loss of diversity, such as phylogenetic and functional diversity, can permanently reduce future options, such as wild species that might be domesticated as new crops and be used for genetic improvement {2.3.5.3}. People have created substitutes for some other contributions of nature, but many of them are imperfect or financially prohibitive {2.3.2.2}. For example, high-quality drinking water can be realized either through ecosystems that filter pollutants or through human-engineered water treatment facilities {2.3.5.3}. Similarly, coastal flooding from storm surges can be reduced either by coastal mangroves or by dikes and sea walls {2.3.5.3}. In both cases, however, built infrastructure can be extremely expensive, incur high future costs and fail to provide synergistic benefits such as nursery habitats for edible fish or recreational opportunities {2.3.5.2}. More generally, human-made replacements often do not provide the full range of benefits provided by nature {2.3.2.2} **(Figure SPM.1)**.

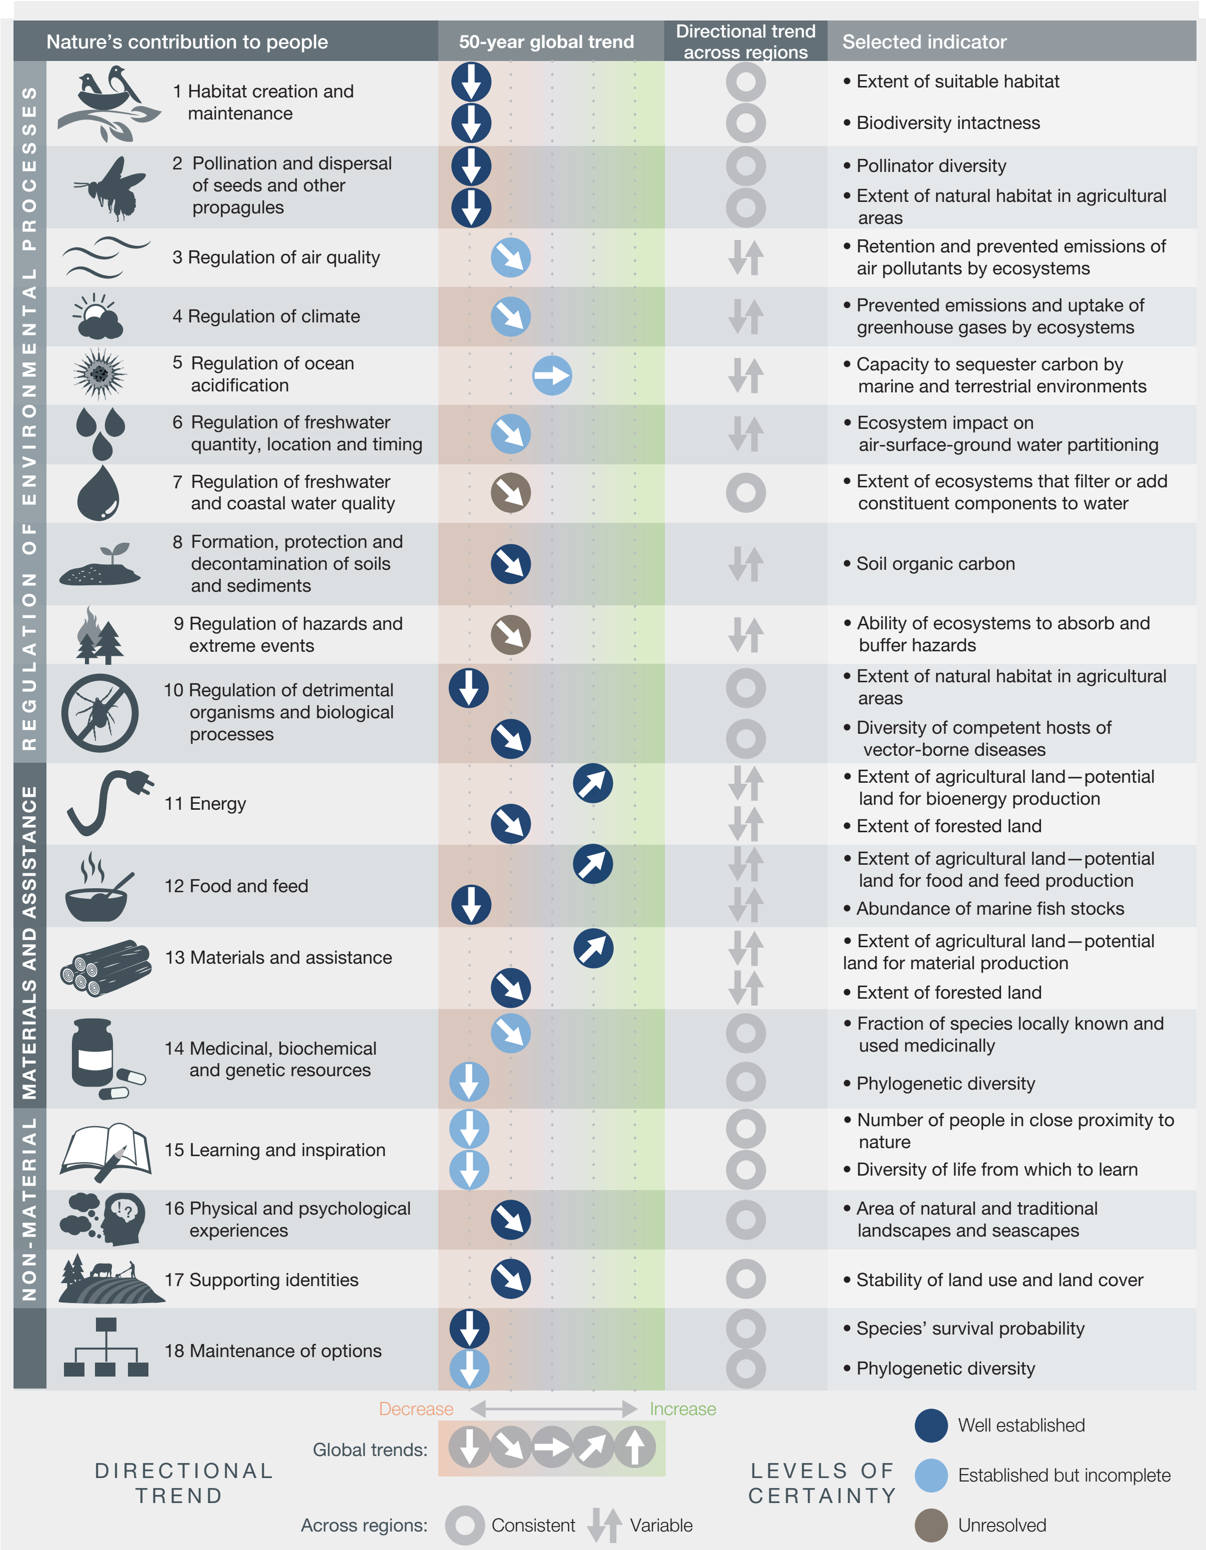

Figure SPM 1 **Global trends in the capacity of nature to sustain contributions to good quality of life from 1970 to the present, which show a decline for 14 of the 18 categories of nature's contributions to people analysed.**

Data supporting global trends and regional variations come from a systematic review of over 2,000 studies {2.3.5.1}. Indicators were selected on the basis of availability of global data, prior use in assessments and alignment with 18 categories. For many categories of nature's contributions, two indicators are included that show different aspects of nature's capacity to contribute to human well-being within that category. Indicators are defined so that an increase in the indicator is associated with an improvement in nature's contributions.

4 Humanity is a dominant global influence on life on earth, and has caused natural terrestrial, freshwater and marine ecosystems to decline (*well established*) {2.2.5.2} (Figure SPM.2). Global indicators of ecosystem extent and condition have shown a decrease by an average of 47 per cent of their estimated natural baselines, with many continuing to decline by at least 4 per cent per decade *(established but incomplete)* {2.2.5.2.1}. On land, particularly sensitive ecosystems include old-growth forests, insular ecosystems, and wetlands; and only around 25 per cent of land is sufficiently unimpacted that ecological and evolutionary processes still operate with minimal human intervention *(established but incomplete)* {2.2.3.4.1, 2.2.5.2.1}. In terrestrial "hotspots" of endemic species, natural habitats have generally undergone greater reductions to date in extent and condition, and tend to be experiencing more rapid ongoing decline, on average than other terrestrial regions {2.2.5.2.1}. Globally, the net rate of forest loss has halved since the 1990s, largely because of net increases in temperate and high latitude forests; high-biodiversity tropical forests continue to dwindle, and global forest area is now approximately 68 per cent of the estimated pre-industrial level *(established but incomplete)* {2.2.5.2.1}. Forests and natural mosaics sufficiently undamaged to be classed as "intact" (defined as being larger than 500 km^2 where satellites can detect no human pressure) were reduced by 7 per cent (919, 000 km^2) between 2000 and 2013, shrinking in both developed and developing countries {2.2.5.2.1}. Inland waters and freshwater ecosystems show among the highest rates of decline. Only 13 per cent of the wetland present in 1700 remained by 2000; recent losses have been even more rapid (0.8 per cent per year from 1970 to 2008) *(established but incomplete)* {2.2.7.9}.

5 Marine ecosystems, from coastal to deep sea, now show the influence of human actions, with coastal marine ecosystems showing both large historical losses of extent and condition as well as rapid ongoing declines (*established but incomplete*) {2.2.5.2.1, 2.2.7.15} (Figure SPM.2). Over 40 per cent of ocean area was strongly affected by multiple drivers in 2008, and 66 per cent was experiencing increasing cumulative impacts in 2014. Only 3 per cent of the ocean was described as free from human pressure in 2014 *(established but incomplete)* {2.2.5.2.1, 3.2.1}. Seagrass meadows decreased in extent by over 10 per cent per decade from 1970 to 2000 *(established but incomplete)* {2.2.5.2.1}. Live coral cover on reefs has nearly halved in the past 150 years, the decline dramatically accelerating over the past two or three decades due to increased water temperature and ocean acidification interacting with and further exacerbating other drivers of loss *(well established)* {2.2.5.2.1}. These coastal marine ecosystems are among the most productive systems globally, and their loss and deterioration reduce their ability to protect shorelines, and the people and species that live there, from storms, as well as their ability to provide sustainable livelihoods *(well established)* {2.2.5.2.1, 2.3.5.2}. Severe impacts to ocean ecosystems are illustrated by 33 per cent of fish stocks being classified as overexploited and greater than 55 per cent of ocean area being subject to industrial fishing *(established but incomplete)* {2.1.11.1, 2.2.5.2.4, 2.2.7.16}.

6 The global rate of species extinction is already at least tens to hundreds of times higher than the average rate over the past 10 million years and is accelerating (*established but incomplete*) {2.2.5.2.4} (Figure SPM.3). Human actions have already driven at least 680 vertebrate species to extinction since 1500, including the Pinta Giant Tortoise in the Galapagos in 2012, even though successful conservation efforts have saved from extinction at least 26 bird species and 6 ungulate species, including the Arabian Oryx and Przewalski's Horse {3.2.1}. The threat of extinction is also accelerating: in the best-studied taxonomic groups, most of the total extinction risk to species is estimated to have arisen in the past 40 years *(established but incomplete)* {2.2.5.2.4}. The proportion of species currently threatened with extinction according to the International Union for the Conservation of Nature's Red List criteria averages around 25 per cent across the many terrestrial, freshwater and marine vertebrate, invertebrate and plant groups that have been studied in sufficient detail to support a robust overall estimate *(established but incomplete)* {2.2.5.2.4, 3.2}. More than 40 per cent of amphibian species, almost a third of reef-forming corals, sharks and shark relatives and over a third of marine mammals are currently threatened {2.2.5.2.4, 3}. The proportion of insect species threatened with extinction is a key uncertainty, but available evidence supports a tentative estimate of 10 per cent *(established but incomplete)* {2.2.5.2.4}. Those proportions suggest that, of an estimated 8 million animal and plant species (75 per cent of which are insects), around 1 million are threatened with extinction *(established but incomplete)* {2.2.5.2.4}. A similar picture also emerges from an entirely separate line of evidence. Habitat loss and deterioration, largely caused by human actions, have reduced global terrestrial habitat integrity by 30 per cent relative to an unimpacted baseline; combining that with the longstanding relationship between habitat area and species numbers suggests that around 9 per cent of the world's estimated 5.9 million terrestrial species – more than 500,000 species – have insufficient habitat for long-term survival, and are committed to extinction, many within decades, unless their habitats are restored *(established but incomplete)* {2.2.5.2.4}. Population declines often give warning that a species' risk of extinction is increasing. The Living Planet Index, which synthesises trends in vertebrate populations, shows that species have declined rapidly since 1970, with reductions of 40 per cent for terrestrial species, 84 per cent for freshwater species and 35 per cent for marine species *(established but*

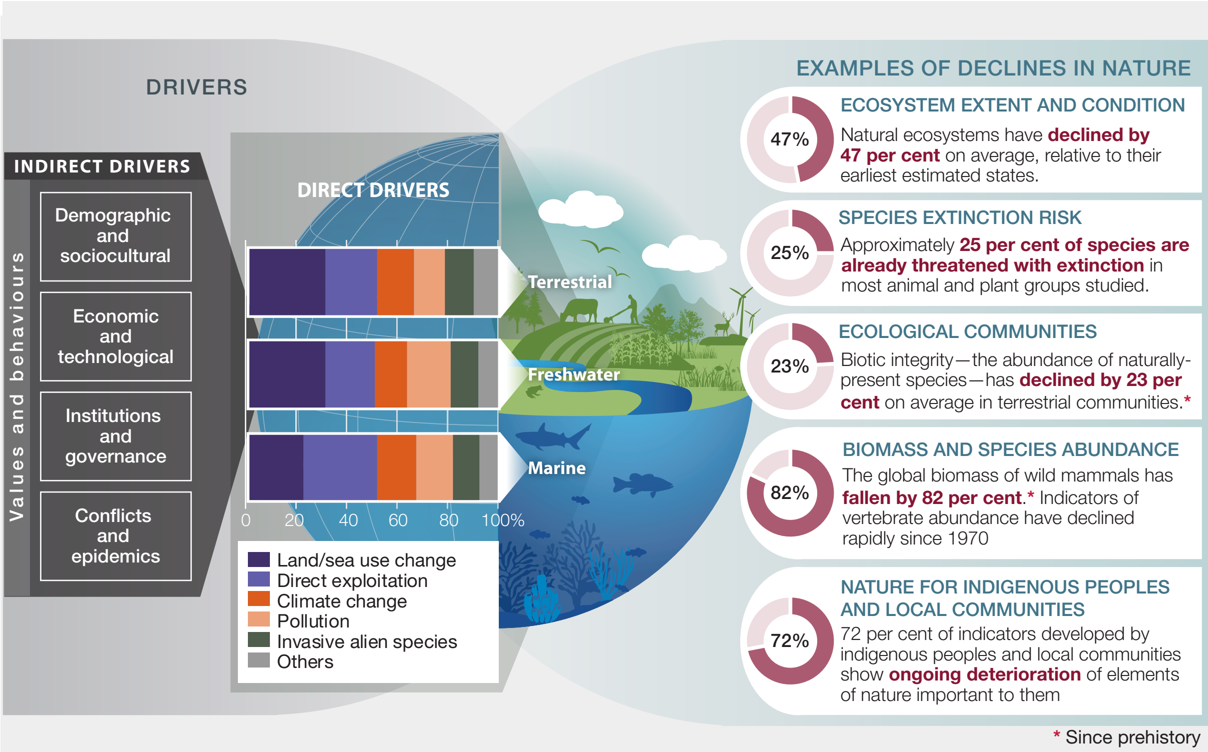

Figure SPM 2 **Examples of global declines in nature, emphasizing declines in biodiversity, that have been and are being caused by direct and indirect drivers of change.**

The direct drivers (land-/sea-use change; direct exploitation of organisms; climate change; pollution; and invasive alien species)[7] result from an array of underlying societal causes[8]. These causes can be demographic (e.g., human population dynamics), sociocultural (e.g., consumption patterns), economic (e.g., trade), technological, or relating to institutions, governance, conflicts and epidemics. They are called indirect drivers[9] and are underpinned by societal values and behaviours. The colour bands represent the relative global impact of direct drivers, from top to bottom, on terrestrial, freshwater and marine nature, as estimated from a global systematic review of studies published since 2005. Land- and sea-use change and direct exploitation account for more than 50 per cent of the global impact on land, in fresh water and in the sea, but each driver is dominant in certain contexts {2.2.6}. The circles illustrate the magnitude of the negative human impacts on a diverse selection of aspects of nature over a range of different time scales based on a global synthesis of indicators {2.2.5, 2.2.7}.

incomplete) {2.2.5.2.4}. Local declines of insect populations such as wild bees and butterflies have often been reported, and insect abundance has declined very rapidly in some places even without large-scale land-use change, but the global extent of such declines is not known *(established but incomplete)* {2.2.5.2.4}. On land, wild species that are endemic (narrowly distributed) have typically seen larger-than-average changes to their habitats and shown faster-than-average declines *(established but incomplete)* {2.2.5.2.3, 2.2.5.2.4}.

7 The number of local varieties and breeds of domesticated plants and animals and their wild relatives has been reduced sharply as a result of land use change, knowledge loss, market preferences and large-scale trade (*well established*) {2.2.5.2.6, 2.2.5.3.1}. Domestic varieties of plants and animals are the result of natural and human-managed selection, sometimes over centuries or millennia, and tend to show a high degree of adaptation (genotypic and phenotypic) to local conditions *(well established)* {2.2.4.4}. As a result, the pool of genetic variation which underpins food security has declined *(well established)* {2.2.5.2.6}. Ten per cent of domesticated breeds of mammals were recorded as extinct, as well as some 3.5 per cent of domesticated breeds of birds *(well established)* {2.2.5.2.6}. Many hotspots of agrobiodiversity and crop wild relatives are also under threat or not formally protected. The conservation status of wild relatives of domesticated livestock has also deteriorated. These wild relatives represent critical reservoirs of genes and traits that may provide resilience against future climate change, pests and pathogens and may improve current heavily depleted gene pools of many crops and domestic animals {2.2.3.4.3}. The lands of

7. The classification of direct drivers used throughout this assessment is in {2.1.12 - 2.1.17}.
8. The interactions among indirect and direct drivers are addressed in {2.1.11, 2.1.18}.
9. The classification of indirect drivers used throughout this assessment is in {2.1.3 - 2.1.10}.

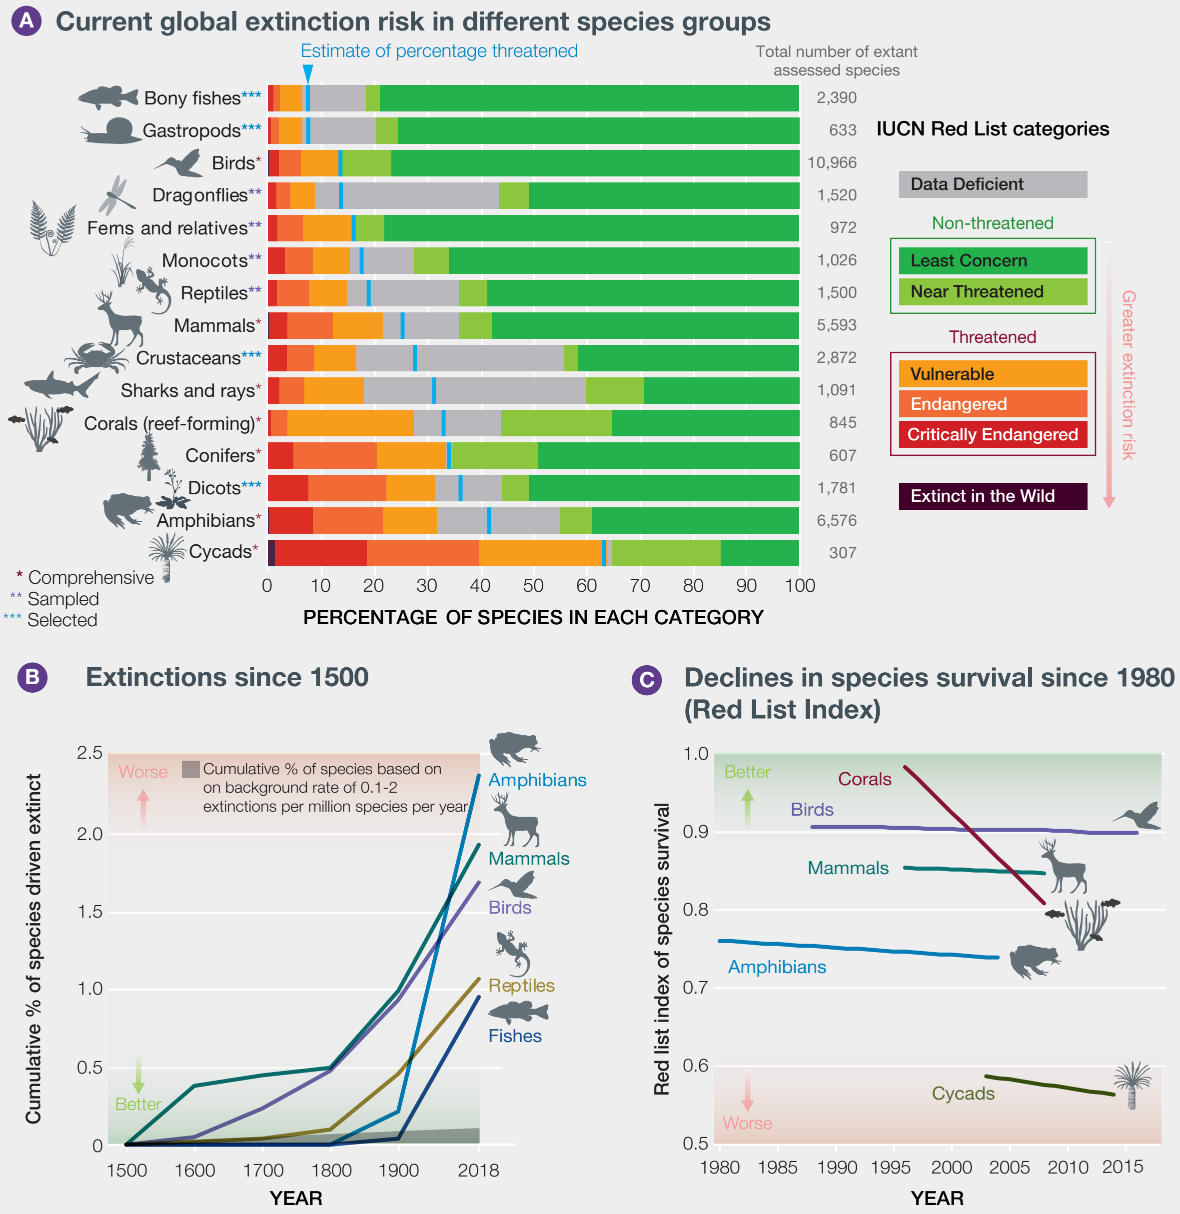

Figure SPM 3 **A substantial proportion of assessed species are threatened with extinction and overall trends are deteriorating, with extinction rates increasing sharply in the past century.**

A Percentage of species threatened with extinction in taxonomic groups that have been assessed comprehensively, or through a 'sampled' approach, or for which selected subsets have been assessed, by the International Union for Conservation of Nature (IUCN) Red List of Threatened Species. Groups are ordered according to the best estimate for the percentage of extant species considered threatened (shown by the vertical blue lines), assuming that data deficient species are as threatened as non-data deficient species. B Extinctions since 1500 for vertebrate groups. Rates for reptiles and fishes have not been assessed for all species. C Red List Index of species survival for taxonomic groups that have been assessed for the IUCN Red List at least twice. A value of 1 is equivalent to all species being categorized as Least Concern; a value of zero is equivalent to all species being classified as Extinct. Data for all panels derive from www.iucnredlist.org (see Chapter 3 Figure 3.4 and Chapter 2 Figure 2.7).

indigenous peoples and local communities, including farmers, pastoralists and herders, are often important areas for *in situ* conservation of the remaining varieties and breeds *(well established)* {2.2.5.3.1}. Available data suggest that genetic diversity within wild species globally has been declining by about 1 per cent per decade since the mid-19th century; and genetic diversity within wild mammals and amphibians tends to be lower in areas where human influence is greater *(established but incomplete)* {2.2.5.2.6}.

8 **Human-driven changes in species diversity within local ecological communities vary widely, depending on the net balance between species loss and the influx of alien species, disturbance-tolerant species, other human-adapted species or climate migrant species (*well established*) {2.2.5.2.3}.** Even though human-dominated landscapes are sometimes species-rich, their species composition is markedly altered from that in natural landscapes *(well established)* {2.2.5.2.3, 2.2.7.10, 2.2.7.11}. As a result of human-caused changes in community composition, naturally occurring species in local terrestrial ecosystems worldwide are estimated to have lost at least 20 per cent of their original abundance on average, with hotspots of endemic species tending to have lost even more *(established but incomplete)* {2.2.5.2.3}. The traits of species influence whether they persist or even thrive in human-modified ecosystems *(well established)* {2.2.3.6, 2.2.5.2.5}. For example, species that are large, grow slowly, are habitat specialists or are carnivores – such as great apes, tropical hardwood trees, sharks and big cats – are disappearing from many areas. Many other species, including those with opposite characteristics, are becoming more abundant locally and are spreading quickly around the world; across a set of 21 countries with detailed records, the numbers of invasive alien species per country have risen by some 70 per cent since 1970 {2.2.5.2.3}. The effects of invasive alien species are often particularly severe for the native species and assemblages on islands and in other settings with high proportions of endemic species *(well established)* {2.2.3.4.1, 2.2.5.2.3}. Invasive alien species can have devastating effects on mainland assemblages as well: for example, a single invasive pathogen species, *Batrachochytrium dendrobatidis*, is a threat to nearly 400 amphibian species worldwide and has already caused a number of extinctions *(well established)* {2.2.5.2.3}. Many drivers add already widespread species to ecological communities in many places; and many drivers cause endemic species to decline in many places. These two processes have contributed to the widespread erosion of differences between ecological communities in different places, a phenomenon known as biotic homogenization or the "anthropogenic blender" *(well established)* {2.2.5.2.3}. The consequences of all these changes for ecosystem processes and hence nature's contributions to people can be very significant. For example, the decline and disappearance of large herbivores and predators has dramatically affected the structure, fire regimes, seed dispersal, land surface albedo and nutrient availability within many ecosystems *(well established)* {2.2.5.2.1}. However, the consequences of changes often depend on details of the ecosystem, remain hard to predict and are still understudied *(established but incomplete)* {2.2.5.2.3}.

9 **Many organisms show ongoing biological evolution so rapid that it is detectable within only a few years or even more quickly – in response to anthropogenic drivers *(well established)* {2.2.5.2.5, 2.2.5.2.6}. Management decisions that take those evolutionary changes into account will be noticeably more effective (*established but incomplete*) {Box 2.5}.** This human-driven contemporary evolution, which has long been recognized in microbes, viruses, agricultural insect pests and weeds *(well established)*, is now being observed in some species within all major taxonomic groups (animals, plants, fungi and microorganisms). Such changes are known to occur in response to human activities or drivers, such as hunting, fishing, harvesting, climate change, ocean acidification, soil and water pollution, invasive species, pathogens, pesticides and urbanization *(established but incomplete)* {2.2.5.2.5}. However, management strategies typically assume that evolutionary changes occur only over much longer time periods and thus ignore rapid evolution. These policy considerations span many spheres in which management actions designed to slow or speed evolution can dramatically change outcomes, as the following examples indicate. Insects, weeds and pathogens evolve resistance to insecticides, herbicides and other control agents, yet management strategies such as refuges, crop rotation, and crop diversity can dramatically slow that undesirable evolution *(well established)* {Box 2.5}. Commercial fish populations have evolved to mature earlier under intensive harvesting, which sometimes can be minimized by mandating changes in fishing gear or fish size limits *(established but incomplete)* {2.2.5.2.5}. Climate change favours the evolution of seasonally earlier reproduction in many organisms, which can in principle be facilitated through the introduction of individuals from populations already adapted to such conditions *(established but incomplete)* {2.2.5.2.5}. Mosquitoes rapidly evolve resistance to efforts to control them, but evolutionarily informed management actions can dramatically slow that undesirable evolution *(established but incomplete)* {2.2.5.2.5}. Contemporary evolution is thus relevant to many policy concerns. Understanding and working with contemporary evolution can address important concerns surrounding pollination and dispersal, coral persistence in the face of ocean acidification, water quality, pest regulation, food production and options for the future *(established but incomplete).* The specific actions taken will typically be case-specific and therefore will require careful assessment of evolutionary potential and consequences. In many cases, the best strategy could be to simply maintain the ability of natural populations to respond evolutionarily on their own – rather than through direct human manipulation of evolution.

B. Direct and indirect drivers of change have accelerated during the past 50 years.

10 Today, humans extract more from the Earth and produce more waste than ever before *(well established*). Globally, land-use change is the direct driver with the largest relative impact on terrestrial and freshwater ecosystems, while direct exploitation of fish and seafood has the largest relative impact in the oceans (*well established*) (Figure SPM.2) {2.2.6.2}. Climate change, pollution and invasive alien species have had a lower relative impact to date but are accelerating (*established but incomplete*) {2.2.6.2, 3.2, 4.2}. Although the pace of agricultural expansion into intact ecosystems {2.1.13} has varied from country to country, losses of intact ecosystems have occurred primarily in the tropics, home to the highest levels of biodiversity on the planet (for example, 100 million hectares of tropical forest from 1980 to 2000), due to cattle ranching in Latin America (~42 million ha) and plantations in South-East Asia (~7.5 million hectares, 80 per cent in oil palm) among others {2.1.13}, noting that plantations can also increase total forest area. Within land-use change, urban areas have more than doubled since 1992. In terms of direct exploitation, approximately 60 billion tons[10] of renewable and non-renewable resources {2.1.2} are being extracted each year. That total has nearly doubled since 1980, as population has grown considerably while the average per capita consumption of materials (e.g., plants, animals, fossil fuels, ores, construction material) has risen by 15 per cent since 1980 *(established but incomplete)* {2.1.6, 2.1.11, 2.1.14}. This activity has generated unprecedented impacts: since 1980, greenhouse gas emissions have doubled {2.1.11, 2.1.12}, raising average global temperatures by at least 0.7 °C {2.1.12}, while plastic pollution in oceans has increased tenfold {2.1.15}. Over 80 per cent of global wastewater is being discharged back into the environment without treatment, while 300–400 million tons of heavy metals, solvents, toxic sludge and other wastes from industrial facilities are dumped into the world's waters each year {2.1.15}. Excessive or inappropriate application of fertilizer can lead to run-off from fields and enter freshwater and coastal ecosystems, producing more than 400 hypoxic zones that affected a total area of more than 245,000 km^2 as early as 2008 {2.1.15}. In some island countries, invasive alien species have a significant impact on biodiversity, with introduced species being a key driver of extinctions.

11 Land-use change is driven primarily by agriculture, forestry and urbanization, all of which are associated with air, water and soil pollution. Over one third of the world's land surface and nearly three-quarters of available freshwater resources are devoted to crop or livestock production {2.1.11}. Crop production occurs on some 12 per cent of total ice-free land. Grazing occurs on about 25 per cent of total ice-free lands and approximately 70 per cent of drylands {2.1.11}. Approximately 25 per cent of the globe's greenhouse gas emissions come from land clearing, crop production and fertilization, with animal-based food contributing 75 per cent of that. Intensive agriculture has increased food production at the cost of regulating and non-material contributions from nature, though environmentally beneficial practices are increasing. Small landholdings (less than 2 hectares) contribute approximately 30 per cent of global crop production and 30 per cent of the global food caloric supply, using around a quarter of agricultural land and usually maintaining rich agrobiodiversity {2.1.11}. Moving to logging, between 1990 and 2015, clearing and wood harvest contributed to a total reduction of 290 million hectares in native forest cover, while the area of planted forests grew by 110 million hectares {2.1.11}. Industrial roundwood harvest is falling within some developed countries but rising on average in developing countries {2.1.11}. Illegal timber harvests and related trade supply 10–15 per cent of global timber, and up to 50 per cent in certain areas, hurting revenues for state owners and livelihoods for the rural poor. All mining on land has increased dramatically and, while still using less than 1 per cent of the Earth's land, has had significant negative impacts on biodiversity, emissions of highly toxic pollutants, water quality and water distribution, and human health {2.1.11}. Mined products contribute more than 60 per cent of the GDP of 81 countries. There are approximately 17,000 large-scale mining sites in 171 countries, with the legal sites mostly managed by international corporations, but there is also extensive illegal and small-scale mining that is harder to trace, and both types of sites are often in locations relevant for biodiversity {2.1.11}.

12 In marine systems, fishing has had the most impact on biodiversity (target species, non-target species and habitats) in the past 50 years alongside other significant drivers *(well established*) {2.1.11, 2.2.6.2} (Figure SPM.2). Global fish catches have been sustained by expanding fishing geographically and penetrating into deeper waters *(well established)* {3.2.1}. An increasing proportion of marine fish stocks are overfished (33 per cent in 2015), including stocks of economically important species, while 60 per cent are maximally sustainably fished and only 7 per cent are underfished *(well established)* {Box 3.1}. Industrial fishing, concentrated in a few countries and corporations {2.1.11}, covers at least 55 per cent of the oceans, largely concentrated in the

10. All references to "tons" are to metric tons.

northeast Atlantic, the northwest Pacific and upwelling regions off South America and West Africa *(established but incomplete)* {2.1.11}. Small-scale fisheries account for more than 90 per cent of commercial fishers (over 30 million people), and nearly half of global fish catch *(established but incomplete)*. In 2011, illegal, unreported or unregulated fishing represented up to one third of the world's reported catch *(established but incomplete)* {2.1.11}. Since 1992, regional fisheries bodies have been adopting sustainable development principles. For instance, more than 170 members of the Food and Agriculture Organization of the United Nations (FAO) adopted the Code of Conduct for Responsible Fisheries in 1995, and as of 1 April 2018, 52 countries and one member organization had become Parties to the Agreement on Port State Measures to Prevent, Deter and Eliminate Illegal, Unreported and Unregulated Fishing, in order to address the depletion of marine fisheries *(established but incomplete)* {2.1.11}, reduce by-catch {3, box 3.3} and lower damage to seabeds and reefs. In addition, the set of established marine protected areas has been growing *(well established)* {2.1.11.1, 2.2.7.16}.

13 **The direct driver with the second highest relative impact on the oceans is the many changes in the uses of the sea and coastal land (*well established*) (Figure SPM.2) {2.2.6.2}.** Coastal habitats, including estuaries and deltas critical for marine biota and regional economies, have been severely affected by sea-use changes (coastal development, offshore aquaculture, mariculture and bottom trawling) and land-use changes (onshore land clearance and urban sprawl along coastlines, plus pollution of rivers). Pollution from land sources is already a major driver of negative environmental change. Ocean mining, while relatively small, has expanded since 1981 to ~ 6,500 offshore oil and gas installations worldwide in 53 countries (60 per cent in the Gulf of Mexico by 2003) and likely will expand into the Arctic and Antarctic regions as the ice melts {2.1.11}. Ocean acidification from increased carbon dioxide levels largely affects shallow waters, with the ecosystems of the subarctic Pacific and western Arctic Ocean particularly affected. Plastic microparticles and nanoparticles are entering food webs in poorly understood ways {2.1.15.3}. Coastal waters hold the highest levels of metals and persistent organic pollutants from industrial discharge and agricultural run-off, poisoning coastal fish harvests. Severe effects from excess nutrient concentrations in certain locations include damage to fish and seabed biota. The dynamics of ocean and airborne transport of pollutants mean that the harm from inputs of plastics, persistent organic pollutants, heavy metals and ocean acidification is felt worldwide, including with consequences for human health.

14 **Climate change is already having an impact on nature, from genes to ecosystems. It poses a growing risk owing to the accelerated pace of change and interactions with other direct drivers (*well established*) {2.1.12, 2.1.18, 2.2.6.2}**. Shifts in species distribution, changes in phenology, altered population dynamics and changes in the composition of species assemblage or the structure and function of ecosystems, are evident {2.2.5.3.2, 2.2.5.2.3, 2.2.6.2} and accelerating in marine, terrestrial and freshwater systems *(well established)* {2.2.3.2}. Almost half (47 per cent) of threatened terrestrial mammals, excluding bats, and one quarter (23 per cent) of threatened birds may have already been negatively affected by climate change in at least part of their distribution (birds in North America and Europe suggest effects of climate change in their population trends since the 1980s) *(established but incomplete)* {2.2.6.2}. Ecosystems such as tundra and taiga and regions such as Greenland, previously little affected by people directly, are increasingly experiencing the impacts of climate change *(well established)* {2.2.7.5}. Large reductions and local extinctions of populations are widespread *(well established)* {2.2.6.2}. This indicates that many species are unable to cope locally with the rapid pace of climate change, through either evolutionary or behavioural processes, and that their continued existence will also depend on the extent to which they are able to disperse, to track suitable climatic conditions, and to preserve their capacity to evolve *(well established)* {2.2.5.2.5}. Many of these changes can have significant impacts on a number of important economic sectors, and cascading effects for other components of biodiversity. Island nations, in particular those in East Asia and the Pacific region, will be most vulnerable to sea-level rise (1m) as projected by all climate change scenarios, {2.1.1.7.1} which will displace close to 40 million people {2.1.1.7.1, 2.2.7.1.8}.

15 **Unsustainable use of the Earth's resources is underpinned by a set of demographic and economic indirect drivers that have increased, and that furthermore interact in complex ways, including through trade (*well established*) {2.1.6}**. The global human population has increased from 3.7 to 7.6 billion since 1970 unevenly across countries and regions, which has strong implications for the degradation of nature. Per capita consumption also has grown, and also is unequal, with wide variations in lifestyles and access to resources across and within regions, plus consequences for nature that are distributed globally through trade. Total gross domestic product is four times higher and is rising faster in developed than in least developed countries. Approximately 821 million people face food insecurity in Asia and Africa, while 40 per cent of the global population lacks access to clean, safe drinking water. Generally, environmentally-based health burdens, such as air and water pollution, are more prevalent in least developed countries {2.1.2, 2.1.15}.

16 **Due to expansions of infrastructure, extensive areas of the planet are being opened up to new threats (*well established*) {2.1.11}**. Globally, paved road lengths are projected to increase by 25 million kilometres by

2050, with nine tenths of all road construction occurring within least developed and developing countries. The number of dams has increased rapidly in the past 50 years. Worldwide, there are now about 50,000 large dams (higher than 15 metres) and approximately 17 million reservoirs (larger than 0.01 hectares or 100m^2) {2.1.11}. The expansions of roads, cities, hydroelectric dams and oil and gas pipelines can come with high environmental and social costs, including deforestation, habitat fragmentation, biodiversity loss, land grabbing, population displacement and social disruption, including for indigenous peoples and local communities *(established but incomplete)*. Yet infrastructure can generate positive economic effects and even environmental gains, based on efficiency, innovation, migration, and urbanization, depending on where and how investment is implemented and governed *(well established)* {2.1.11}. Understanding this variation in impacts is critical.

17 Long-distance transportation of goods and people, including for tourism, have grown dramatically in the past 20 years, with negative consequences for nature overall (*established but incomplete*). The rise in airborne and seaborne transportation of both goods and people, including a threefold increase in travel from developed and developing countries in particular, has increased pollution and significantly increased the presence of invasive alien species *(well established)* {2.1.15}. Between 2009 and 2013, the carbon footprint from tourism rose 40 per cent to 4.5 gigatons of carbon dioxide, and overall, 8 per cent of total greenhouse gas emissions are from tourism-related transportation and food consumption {2.1.11, 2.1.15}. The demand for nature-based tourism or ecotourism has also risen, with mixed effects on nature and local communities, including some potential for contributions to local conservation, in particular when carried out at a smaller scale {2.1.11}.

18 Distant areas of the world are increasingly connected, as consumption, production, and governance decisions increasingly influence materials, waste, energy, and information flows in other countries, generating aggregate economic gains while shifting economic and environmental costs, which can link to conflicts (*established but incomplete*) (Figure SPM.4). As per capita consumption has risen, developed countries and rapidly growing developing countries {2.1.2, 2.1.6}, while at times supporting efficient production for exports, often reduce water consumption and forest degradation nationally {2.1.6, 2.1.11} by importing crops and other resources, mainly from developing countries {2.1.6}. The latter, as a result, see declines in nature and its contributions to people (habitat, climate, air and water quality) different from the exported food, fibre and timber products **(Figures SPM.1 and 5)**. Reduced, declining and unequal access to nature's contributions to people may, in a complex interaction with other factors, be a source of conflict within and among countries *(established but incomplete)*. Least developed countries, often rich in and more dependent upon natural resources, have suffered the greatest land degradation, have also experienced more conflict and lower economic growth, and have contributed to environmental outmigration by several million people {2.1.2, 2.1.4}. When indigenous peoples or local communities are expelled from or threatened on their lands, including by mining or industrial logging for export, this too can spark conflict – often between actors with different levels of power, as today a few actors can control large shares of any market or capital asset rivalling those of most countries {2.1.6}, while funds channelled through tax havens support most vessels implicated in illegal, unreported and unregulated fishing. More than 2,500 conflicts over fossil fuels, water, food and land are currently occurring across the planet, and at least 1,000 environmental activists and journalists were killed between 2002 and 2013 {2.1.11, 2.1.18}.

19 Governance has at many levels moved slowly to further and better incorporate into policies and incentives the values of nature's contributions to people. However, around the globe, subsidies with harmful effects on nature have persisted (*well established*) {2.1, 3, 5, 6.4}. The incorporation by society of the value of nature's contributions to people will entail shifts in governance even within private supply chains, for instance when civil society certifies and helps to reward desired practices, or when States block access to markets because of undesirable practices {2.1.7}. Successful local governance supported by recognition of local rights has often incorporated knowledge of how nature contributes to human wellbeing to motivate such behaviours {2.1.8}. National agencies have also promoted land management strategies that are more sustainable and introduced regulations, among other policy measures {2.1.9.2}, and have coordinated with other nations on global agreements to maintain nature's contributions to people {2.1.10}. Economic instruments that may be harmful to nature include subsidies, financial transfers, subsidized credit, tax abatements, and prices for commodities and industrial goods that hide environmental and social costs. Such instruments favour unsustainable production and, as a consequence, can promote deforestation, overfishing, urban sprawl, and wasteful uses of water. In 2015, agricultural support potentially harmful to nature amounted to $100 billion in countries belonging to the Organization for Economic Cooperation and Development, although some subsidy reforms to reduce unsustainable pesticide uses and adjust several other consequential development practices have been introduced {2.1.9.1, 6.4.5}. Fossil fuel subsidies valued at $345 billion result in global costs of $5 trillion when including the reduction of nature's contributions (coal accounts for about half of these costs, petroleum for about one third and natural gas for about one tenth {2.1.9.1.2}). In fisheries, subsidies to

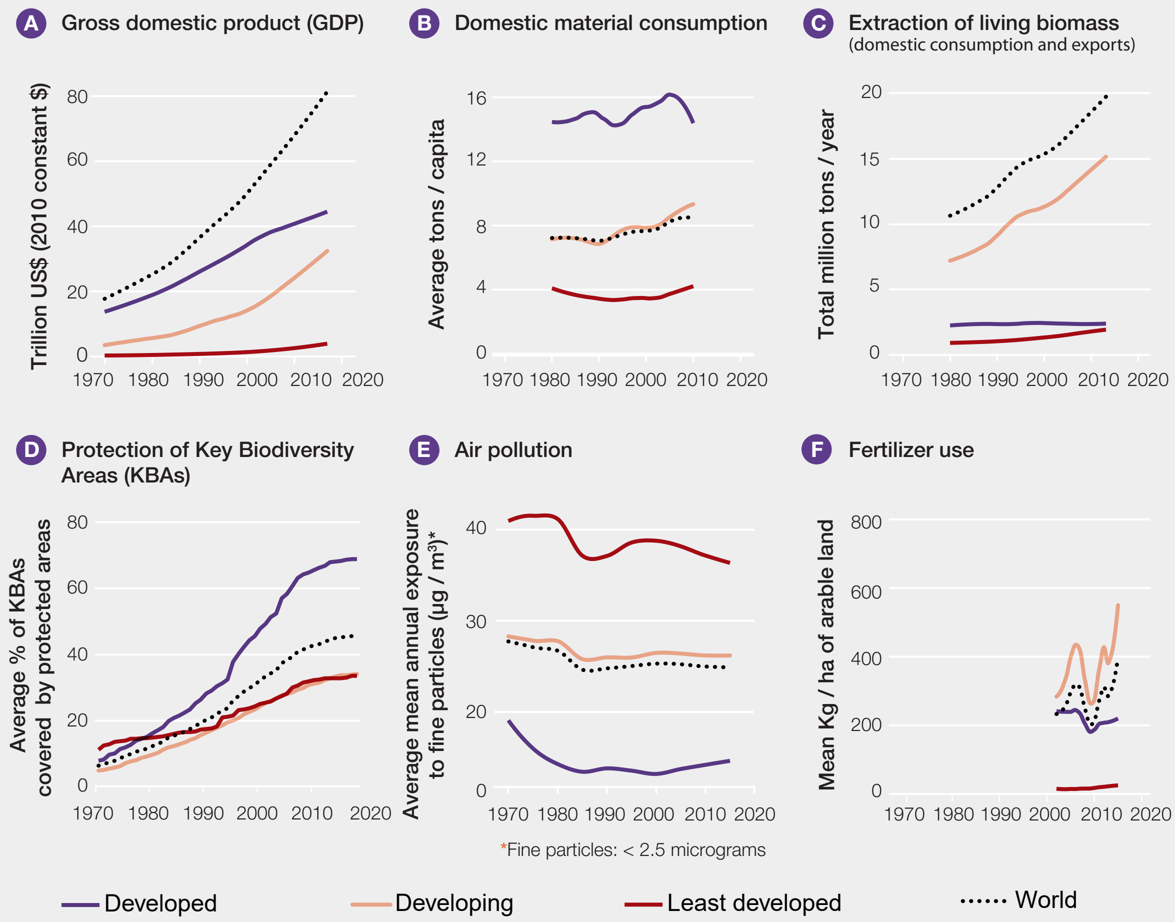

Figure SPM 4 **Development pathways since 1970 for selected key indicators of human-environment interactions, which show a large increase in the scale of global economic growth and its impacts on nature, with strong contrasts across developed, developing, and least developed countries.**

Countries are classified according to the United Nations World Economic Situation and Prospects (https://www.un.org/development/desa/dpad/publication/world-economic-situation-and-prospects-2019/). Global gross domestic product has risen fourfold in real terms, with the vast majority of growth occurring in developed and developing countries A. Extraction of living biomass (e.g., crops, fish) to meet the demand for domestic consumption and for export is highest in developing countries and rising rapidly B. However, material consumption per capita within each country (from imports and domestic production) is highest in developed countries. Overall protection of Key Biodiversity Areas is rising, being highest within developed countries D. Air pollution is highest in least developed countries E, while the challenges of non-point-source pollution from the use of fertilizers are highest in developing countries. Data sources: A, E, F: www.data.worldbank.org; B, C: www.materialflows.net; D: www.keybiodiversityareas.org, www.protectedplanet.net.

increase and maintain capacity, which in turn often lead to the degradation of nature, constitute perhaps a majority of the tens of US$ billions spent on supports {5.3.2.5}.

20 Much of the world's terrestrial wild and domesticated biodiversity lies in areas traditionally managed, owned, used or occupied by indigenous peoples and local communities (*well established*) (Figure SPM.5) {2.2.4}. In spite of efforts at all levels, although nature on indigenous lands is declining less rapidly than elsewhere, biodiversity and the knowledge associated with its management are still deteriorating (*established but incomplete*) {2.2.4, 2.2.5.3}. Despite a long history of resource use, conservation conflicts related to colonial expansion and land appropriation for parks and other uses {3.2} *(well established)*, indigenous peoples and local communities have often managed their landscapes and seascapes in ways that were adjusted to local conditions over generations. These management methods often remain compatible with, or actively support, biodiversity conservation by "accompanying" natural processes with anthropogenic assets *(established but incomplete)* {2.2.4, 2.2.5.3.1} **(Figure SPM.5)**.

Figure SPM 5 **Contributions of indigenous peoples and local communities to the enhancement and maintenance of wild and domesticated biodiversity and landscapes. Indigenous and local knowledge systems are locally based, but regionally manifested and thus globally relevant.**

A wide diversity of practices actively and positively contributes to wild and domestic biodiversity through "accompanying" natural processes with anthropogenic assets (knowledge, practices and technology). Indigenous peoples often manage the land and coastal areas based on culturally specific world views, applying principles and indicators such as the health of the land, caring for the country and reciprocal responsibility. As lifestyles, values and external pressures change with globalization, however, unsustainable practices are becoming increasingly common in certain regions[11]. The image in the centre of the above figure shows the global overlap between 1) land areas traditionally owned, managed[11], used, or occupied by indigenous peoples; 2) formally designated protected areas; and 3) remaining terrestrial areas with very low human intervention (areas that score <4 on the Human Footprint Index[12]). Circles and overlapping sections are proportional in area. Land areas traditionally owned, managed[13], used, or occupied by indigenous peoples overlap with approximately 35 per cent of the area that is formally protected, and approximately 35 per cent of all remaining terrestrial areas with very low human intervention. The topics and pictures in the figure aim to illustrate, not represent, the types and diversity of the following contributions of indigenous peoples and local communities to biodiversity: a domestication and maintenance of locally adapted crop and fruit varieties (potatoes, Peru) and b animal breeds (rider and sheep, Kyrgyzstan) {2.2.4.4}; c creation of species-rich habitats and high ecosystem diversity in cultural landscapes (hay meadows, Central Europe) {2.2.4.1-2}; d identification of useful plants and their cultivation in high-diversity ecosystems (multi-species forest garden, Indonesia) {2.2.4.3}; e and f management and monitoring of wild species, habitats and landscapes for wildlife and for increased resilience (e - Australia, f - Alaska) {2.2.4.5-6}; g restoration of degraded lands (Niger) {3.2.4}; h prevention of deforestation in recognized indigenous territories (Amazon basin, Brazil) {2.2.4.7}; i offering alternative concepts of relations between humanity and nature (Northern Australia).

11. In Stephen Garnett *et al.*, "A spatial overview of the global importance of Indigenous lands for conservation", *Nature Sustainability*, Vol. 1 (July 2018) pp. 369–374.

12. These data sources define land management here as the process of determining the use, development and care of land resources in a manner that fulfils material and non-material cultural needs, including livelihood activities such as hunting, fishing, gathering, resource harvesting, pastoralism, and small-scale agriculture and horticulture.

13. Venter, O. *et al.* Global terrestrial Human Footprint maps for 1993 and 2009. Sci. Data 3, sdata201667 (2016).

At least one quarter of the global land area is traditionally managed[14], owned, used or occupied by indigenous peoples. These areas include approximately 35 per cent of the area that is formally protected, and approximately 35 per cent of all remaining terrestrial areas with very low human intervention *(established but incomplete)* {2.2.5.3.1}. Community-based conservation institutions and local governance regimes have often been effective, at times even more effective than formally established protected areas, in preventing habitat loss *(established but incomplete)*. Several studies have highlighted contributions by indigenous peoples and local communities in limiting deforestation, as well as initiatives showing synergies between these different mechanisms *(well established)* {6.3.2, 2.2.5.3}. In many regions, however, the lands of indigenous peoples are becoming islands of biological and cultural diversity surrounded by areas in which nature has further deteriorated *(established but incomplete)* {2.2.5.3}. Among the local indicators developed and used by indigenous peoples and local communities, 72 per cent show negative trends in nature that underpinned local livelihoods *(established but incomplete)* {2.2.5.3.2}. Major trends include declining availability of resources – due in part to legal and illegal territory reductions, despite expanding indigenous populations – as well as declining health and populations of culturally important species; new pests and invasive alien species as climate changes; losses in both natural forest habitats and grazing lands; and declining productivity in remnant ecosystems. A more detailed global synthesis of trends in nature observed by indigenous peoples and local communities is hindered by the lack of institutions that gather data for these locations and then synthesize them within regional and global summaries {2.2.2}.

14. These data sources define land management here as the process of determining the use, development and care of land resources in a manner that fulfils material and non-material cultural needs, including livelihood activities such as hunting, fishing, gathering, resource harvesting, pastoralism, and small-scale agriculture and horticulture.

C. Goals for conserving and sustainably using nature and achieving sustainability cannot be met by current trajectories, and goals for 2030 and beyond may only be achieved through transformative changes[15] across economic, social, political and technological factors.

21 There has been good progress towards the components of 4 of the 20 Aichi Biodiversity Targets under the Strategic Plan for Biodiversity 2011–2020. Moderate progress has been achieved towards some components of 7 more targets, but for 6 others, poor progress has been made towards all components. There is insufficient information to assess progress towards some or all components of the remaining 3 targets (*established but incomplete*) {3.2}. Overall, the state of nature continues to decline (12 of 16 indicators show significantly worsening trends) (*well established*) {3.2} (Figure SPM.6).

By 2015, greater progress had been made in implementing policy responses and actions to conserve biodiversity for drivers with an impact on coral reefs and other ecosystems vulnerable to climate change (*established but incomplete*) *{3.2}.* Anthropogenic drivers of biodiversity loss, including habitat loss as a result of land-use and sea use change (addressed by Aichi Target 5), unsustainable agriculture, aquaculture and forestry (Aichi Target 7), unsustainable fishing (Aichi Target 6), pollution (Aichi Target 8), and invasive alien species (Aichi Target 9) are increasing globally, despite national efforts to meet the Aichi Targets *(established but incomplete)* {3.2}.

15. A fundamental, system-wide reorganization across technological, economic and social factors, including paradigms, goals and values.

22 Conservation actions, including protected areas, efforts to manage unsustainable use and address the illegal capture and trade of species, and the translocation and eradication of invasive species, have been successful in preventing the extinction of some species (*established but incomplete*). For example, conservation investment during the period between 1996 and 2008 reduced the extinction risk for mammals and birds in 109 countries by a median value of 29 per cent per country, while the rate of decrease in extinction risk for birds, mammals and amphibians would have been at least 20 per cent higher without conservation action in recent decades. Similarly, it is likely that at least 6 species of ungulate (e.g., the Arabian Oryx and Przewalski's Horse) would now be extinct or surviving only in captivity without conservation measures. At least 107 highly threatened birds, mammals and reptiles (e.g., the Island Fox and the Seychelles Magpie-Robin) are estimated to have benefited from invasive mammal eradication on islands {3.2.2}. Although still few and spatially localized, such cases show that with prompt and appropriate action, it is possible to reduce human-induced extinction rates

Goal	Target	Target element (abbreviated)	Progress towards the Aichi Targets		
			Poor	Moderate	Good
A. Address the underlying drivers	1	1.1 Awareness of biodiversity		■	
		1.2 Awareness of steps to conserve		■	
	2	2.1 Biodiversity integrated into poverty reduction		■	
		2.2 Biodiversity integrated into planning		■	
		2.3 Biodiversity integrated into accounting	■		
		2.4 Biodiversity integrated into reporting	■		
	3	3.1 Harmful subsidies eliminated and reformed	■		
		3.2 Positive incentives developed and implemented	■		
	4	4.1 Sustainable production and consumption	■		
		4.2 Use within safe ecological limits	■		
B. Reduce direct pressures	5	5.1 Habitat loss at least halved	■		
		5.2 Degradation and fragmentation reduced	■		
	6	6.1 Fish stocks harvested sustainably	■		
		6.2 Recovery plans for depleted species	Unknown		
		6.3 Fisheries have no adverse impact	■		
	7	7.1 Agriculture is sustainable	■		
		7.2 Aquaculture is sustainable	■		
		7.3 Forestry is sustainable		■	
	8	8.1 Pollution not detrimental	■		
		8.2 Excess nutrients not detrimental	■		
	9	9.1 Invasive alien species prioritized			■
		9.2 Invasive alien pathways prioritized	Unknown		
		9.3 Invasive species controlled or eradicated	■		
		9.4 Invasive introduction pathways managed	■		
	10	10.1 Pressures on coral reefs minimized	■		
		10.2 Pressures on vulnerable ecosystems minimized	■		
C. Improve biodiversity status	11	11.1 10 per cent of marine areas conserved			■
		11.2 17 per cent of terrestrial areas conserved			■
		11.3 Areas of importance conserved		■	
		11.4 Protected areas, ecologically representative		■	
		11.5 Protected areas, effectively and equitably managed		■	
		11.6 Protected areas, well-connected and integrated		■	
	12	12.1 Extinctions prevented	■		
		12.2 Conservation status of threatened species improved	■		
	13	13.1 Genetic diversity of cultivated plants maintained		■	
		13.2 Genetic diversity of farmed animals maintained		■	
		13.3 Genetic diversity of wild relatives maintained		■	
		13.4 Genetic diversity of valuable species maintained	Unknown		
		13.5 Genetic erosion minimized		■	
D. Enhance benefits to all	14	14.1 Ecosystems providing services restored and safeguarded	■		
		14.2 Taking account of women, IPLCs, and other groups	Unknown		
	15	15.1 Ecosystem resilience enhanced	Unknown		
		15.2 15 per cent of degraded ecosystems restored	Unknown		
	16	16.1 Nagoya Protocol in force			■
		16.2 Nagoya Protocol operational		■	
E. Enhance implementation	17	17.1 NBSAPs developed and updated			■
		17.2 NBSAPs adopted as policy instruments		■	
		17.3 NBSAPs implemented		■	
	18	18.1 ILK and customary use respected		■	
		18.2 ILK and customary use integrated	Unknown		
		18.3 IPLCs participate effectively	Unknown		
	19	19.1 Biodiversity science improved and shared		■	
		19.2 Biodiversity science applied	Unknown		
	20	20.1 Financial resources for Strategic Plan[a] increased		■	

Abbreviations: ILK: indigenous and local knowledge; IPLCs: indigenous peoples and local communities; NBSAPs: national biodiversity strategies and action plans.
[a] Strategic Plan for Biodiversity 2011–2020.

Figure SPM 6 **Summary of progress towards the Aichi Targets.**

Scores are based on a quantitative analysis of indicators, a systematic review of the literature, the fifth National Reports to the Convention on Biological Diversity and the information available on countries' stated intentions to implement additional actions by 2020. Progress towards target elements is scored as "Good" (substantial positive trends at a global scale relating to most aspects of the element); "Moderate" (the overall global trend is positive, but insubstantial or insufficient, or there may be substantial positive trends for some aspects of the element, but little or no progress for others; or the trends are positive in some geographic regions, but not in others); "Poor" (little or no progress towards the element or movement away from it; or, despite local, national or case-specific successes and positive trends for some aspects, the overall global trend shows little or negative progress); or "Unknown" (insufficient information to score progress).

(established but incomplete) {2.2.5.2.4, 4}. There are, however, few other counterfactual studies assessing how trends in the state of nature or pressures upon nature would have been different in the absence of conservation efforts *(well established)* {3.2}.

23 **Biodiversity and ecosystem functions and services directly underpin the achievement of several of the Sustainable Development Goals, including those on water and sanitation, climate action, life below water and life on land (Sustainable Development Goals 6, 13, 14 and 15), *(well established)* {3.3.2.1}. Nature also plays an important and complex role in the achievement of the Sustainable Development Goals related to poverty, hunger, health and well-being and sustainable cities (Sustainable Development Goals 1, 2, 3 and 11) *(established but incomplete)* {3.3.2.2} (Figure SPM.7).** Several examples illustrate the interdependencies between nature and the Sustainable Development Goals. For example, nature and its contributions may play an important role in reducing vulnerability to climate-related extreme events and other economic, social and environmental shocks and disasters, although anthropogenic assets are also involved *(established but incomplete)*. Nature's underpinning of specific health targets varies across regions and ecosystems, is influenced by anthropogenic assets and remains understudied. The relationship can be positive or negative, as in the case of certain aspects of biodiversity and infectious diseases (see paragraph 2 of the present document). Nature directly underpins the livelihoods of indigenous peoples and local communities and the rural and urban poor, largely through direct consumption or through the income generated by trade in material contributions such as food (see paragraphs 2 and 36 of the present document) and energy *(well established)*. Such contributions are generally underrepresented in poverty analyses *(established but incomplete)*. Nature and its contributions are also relevant to the Goals for education, gender equality, reducing inequalities and promoting peace, justice and strong institutions (Sustainable Development Goals 4, 5, 10 and 16), but the current focus and wording of the related targets obscures or omits their relationship to nature *(established but incomplete)*.

24 **To achieve the Sustainable Development Goals and the 2050 Vision for Biodiversity, future targets are likely to be more effective if they take into account the impacts of climate change *(well established)* {3.2, 3.3}.** For example, climate change is projected to greatly increase the number of species under threat, with fewer species expanding their ranges or experiencing more suitable climatic conditions than the number of species experiencing range contraction or less suitable conditions *(established but incomplete)* {4.2, 3.2}. The impact of climate change on the effectiveness of protected areas calls for a re-evaluation of conservation objectives; meanwhile, there are currently few protected areas whose objectives and management take climate change into account *(established but incomplete)*. The Sustainable Development Goals for poverty, health, water and food security, and sustainability targets are closely linked through the impacts of multiple direct drivers, including climate change, on biodiversity and ecosystem functions and services, nature and nature's contributions to people and good quality of life. In a post-2020 global biodiversity framework, placing greater emphasis on the interactions between the targets of the Sustainable Development Goals {4.6, 3.7} may provide a way forward for achieving multiple targets, as synergies (and trade-offs) can be considered. Future targets are expected to be more effective if they take into account the impacts of climate change, including on biodiversity, and action to mitigate and adapt to climate change {4.6, 3.7}.

25 **The adverse impacts of climate change on biodiversity are projected to increase with increasing warming, so limiting global warming to well below 2°C would have multiple co-benefits for nature and nature's contributions to people and quality of life; however, it is projected that some large-scale land-based mitigation measures to achieve that objective will have significant impacts on biodiversity *(established but***

Selected Sustainable Development Goals	Selected targets (abbreviated)	Recent status and trends in aspects of nature and nature's contributions to people that support progress towards target *		Uncertain relationship
		Poor/Declining support	Partial support	
No poverty	1.1 Eradicate extreme poverty			U
	1.2 Halve the proportion of people in poverty			U
	1.4 Ensure that all have equal rights to economic resources	■		
	1.5 Build the resilience of the poor	■		
Zero hunger	2.1 End hunger and ensure access to food all year round		■	
	2.3 Double productivity and incomes of small-scale food producers		■	
	2.4 Ensure sustainable food production systems	■		
	2.5 Maintain genetic diversity of cultivated plants and farmed animals		■	
Good health and well-being	3.2 End preventable deaths of newborns and children			U
	3.3 End AIDS, tuberculosis, malaria and neglected tropical diseases			U
	3.4 Reduce premature mortality from non-communicable diseases	Unknown		
	3.9 Reduce deaths and illnesses from pollution	Unknown		
Clean water and sanitation	6.3 Improve water quality	■		
	6.4 Increase water use and ensure sustainable withdrawals	■		
	6.5 Implement integrated water resource management		■	
	6.6 Protect and restore water-related ecosystems	■		
Sustainable cities and communities	11.3 Enhance inclusive and sustainable urbanization	■		
	11.4 Protect and safeguard cultural and natural heritage		■	
	11.5 Reduce deaths and the number of people affected by disasters	■		
	11.6 Reduce the adverse environmental impact of cities	■		
	11.7 Provide universal access to green and public spaces	■		
Climate action	13.1 Strengthen resilience to climate-related hazards	■		
	13.2 Integrate climate change into policies, strategies and planning		■	
	13.3 Improve education and capacity on mitigation and adaptation	Unknown		
	13a Mobilize US$100 billion/year for mitigation by developing countries	Unknown		
	13b Raise capacity for climate change planning and management	Unknown		
Life below water	14.1 Prevent and reduce marine pollution	■		
	14.2 Sustainably manage and protect marine and coastal ecosystems		■	
	14.3 Minimize and address ocean acidification	■		
	14.4 Regulate harvesting and end overfishing		■	
	14.5 Conserve at least 10 per cent of coastal and marine areas		■	
	14.6 Prohibit subsidies contributing to overfishing	■		
	14.7 Increase economic benefits from sustainable use of marine resources	■		
Life on land	15.1 Ensure conservation of terrestrial and freshwater ecosystems	■		
	15.2 Sustainably manage and restore degraded forests and halt deforestation	■		
	15.3 Combat desertification and restore degraded land	■		
	15.4 Conserve mountain ecosystems		■	
	15.5 Reduce degradation of natural habitats and prevent extinctions	■		
	15.6 Promote fair sharing of benefits from use of genetic resources		■	
	15.7 End poaching and trafficking	■		
	15.8 Prevent introduction and reduce impact of invasive alien species	■		
	15.9 Integrate biodiversity values into planning and poverty reduction		■	
	15a Increase financial resources to conserve and sustainably use biodiversity		■	
	15b Mobilize resources for sustainable forest management		■	

* There were no targets that were scored as good/positive status and trends

Figure SPM 7 **Summary of recent status and trends in aspects of nature and nature's contributions to people that support progress towards achieving selected targets of the Sustainable Development Goals.**

The targets selected are those where the current evidence and wording of the target make it possible to assess the consequences of the trends in nature and nature's contribution to people as they relate to the achievement of the target. Chapter 3, Section 3.3 provides an assessment of the evidence of the links between nature and the Sustainable Development Goals. The scores for the targets are based on a systematic assessment of the literature and a quantitative analysis of the indicators, where possible. None of the targets scored "Full support" (that is, having a good status or substantial positive trends on a global scale). Consequently, the score of "Full support" was not included in the table. "Partial support" means that the overall global status and trends are positive, but still insubstantial or insufficient; or there may be substantial positive trends for some relevant aspects, but negative trends for others; or the trends are positive in some geographic regions, but negative in others. "Poor/Declining support" indicates poor status or substantial negative trends at a global scale. "Uncertain relationship" means that the relationship between nature and/or nature's contributions to people and the achievement of the target is uncertain. "Unknown" indicates that there is insufficient information to score the status and trends.

***incomplete)* {4.2, 4.3, 4.4, 4.5}.** All climate model trajectories show that limiting human-induced climate change to well below 2°C requires immediate, rapid reductions in greenhouse gas emissions or a reliance on substantial carbon dioxide removal from the atmosphere. However, the land areas required for bioenergy crops (with or without carbon capture and storage), afforestation and reforestation to achieve the targeted carbon uptake rates are projected to be very large {4.2.4.3., 4.5.3}. The biodiversity and environmental impact of large-scale afforestation and reforestation depends to a large degree on where these occur (prior vegetation cover, state of degradation), and the tree species planted *(established but incomplete)*. Likewise, large bioenergy crop or afforested areas are expected to compete with areas set aside for conservation, including restoration, or agriculture *(established but incomplete)*. Consequently, large-scale land-based mitigation measures may jeopardize the achievement of other Sustainable Development Goals that depend on land resources *(well established)* {4.5.3}. In contrast, the benefits of avoiding and reducing deforestation and promoting restoration can be significant for biodiversity *(well established)* and are expected to have co-benefits for local communities *(established but incomplete)* {4.2.4.3}.

26 Biodiversity and nature's regulating contributions to people are projected to decline further in most scenarios of global change over the coming decades, while the supply and demand for nature's material contributions to people that have current market value (food, feed, timber and bioenergy) are projected to increase (*well established*) {4.2, 4.3} (for example, see **Figure SPM.8**). These changes arise from continued human population growth, increasing purchasing power, and increasing per capita consumption. The projected effects of climate change and land use change on terrestrial and freshwater biodiversity are mostly negative, increase with the degree of global warming and land use change, and have an impact on marine biodiversity through increased eutrophication and deoxygenation of coastal waters *(well established)* {4.2.2.3.2, 4.2.3, 4.2.4}. For instance, a synthesis of many studies estimates that the fraction of species at risk of extinction due to climate change is 5 per cent at 2°C warming, rising to 16 per cent at 4.3°C warming {4.2.1.1}. Climate change and business-as-usual fishing scenarios are expected to worsen the status of marine biodiversity *(well established)* {4.2.2.2, 4.2.2.3.1}. Climate change alone is projected to decrease ocean net primary production by between 3 and 10 per cent, and fish biomass by between 3 and 25 per cent (in low and high warming scenarios, respectively) by the end of the century *(established but incomplete)* {4.2.2.2.1}. Whether or not the current removal of nearly 30 per cent of anthropogenic carbon dioxide emissions by terrestrial ecosystems continues into the future varies greatly from one scenario to the next and depends heavily on how climate change, atmospheric carbon dioxide and land-use change interact. Important regulating contributions of nature, such as coastal and soil protection, crop pollination and carbon storage, are projected to decline *(established but incomplete)* {4.2.4, 4.3.2.1}. In contrast, substantial increases in food, feed, timber and bioenergy production are predicted in most scenarios *(well established)* {4.2.4, 4.3.2.2}. Scenarios that include substantial shifts towards sustainable management of resource exploitation and land use, market reform, globally equitable and moderate animal protein consumption, and reduction of food waste and losses result in low loss or even recovery of biodiversity *(well established)* {4.2.2.3.1, 4.2.4.2, 4.3.2.2, 4.5.3}.

27 The magnitude of the impacts on biodiversity and ecosystem functions and services and the differences between regions are smaller in scenarios that focus on global or regional sustainability (*well established*) (Figure SPM.8). Sustainability scenarios that explore moderate and equitable consumption result in substantially lower negative impacts on biodiversity and ecosystems due to food, feed and timber production *(well established)* {4.1.3, 4.2.4.2, 4.3.2, 4.5.3}. The general patterns at the global level – namely, declines in biodiversity and regulating contributions versus increases in the production of food, bioenergy and materials – are evident in nearly all subregions {4.2.2, 4.2.3, 4.2.4, 4.3.3}. For terrestrial systems, most studies indicate that South America, Africa and parts of Asia will be much more significantly affected than other regions, especially in scenarios that are not based on sustainability objectives (see **Figure SPM.8** as an example). That is due in part to regional climate change differences and in part to the fact that scenarios generally foresee the largest land use conversions to crops or bioenergy in those regions {4.1.5, 4.2.4.2}. Regions such as North America and Europe are expected to have low conversion to crops and continued reforestation {4.1.5, 4.2.4.2}.

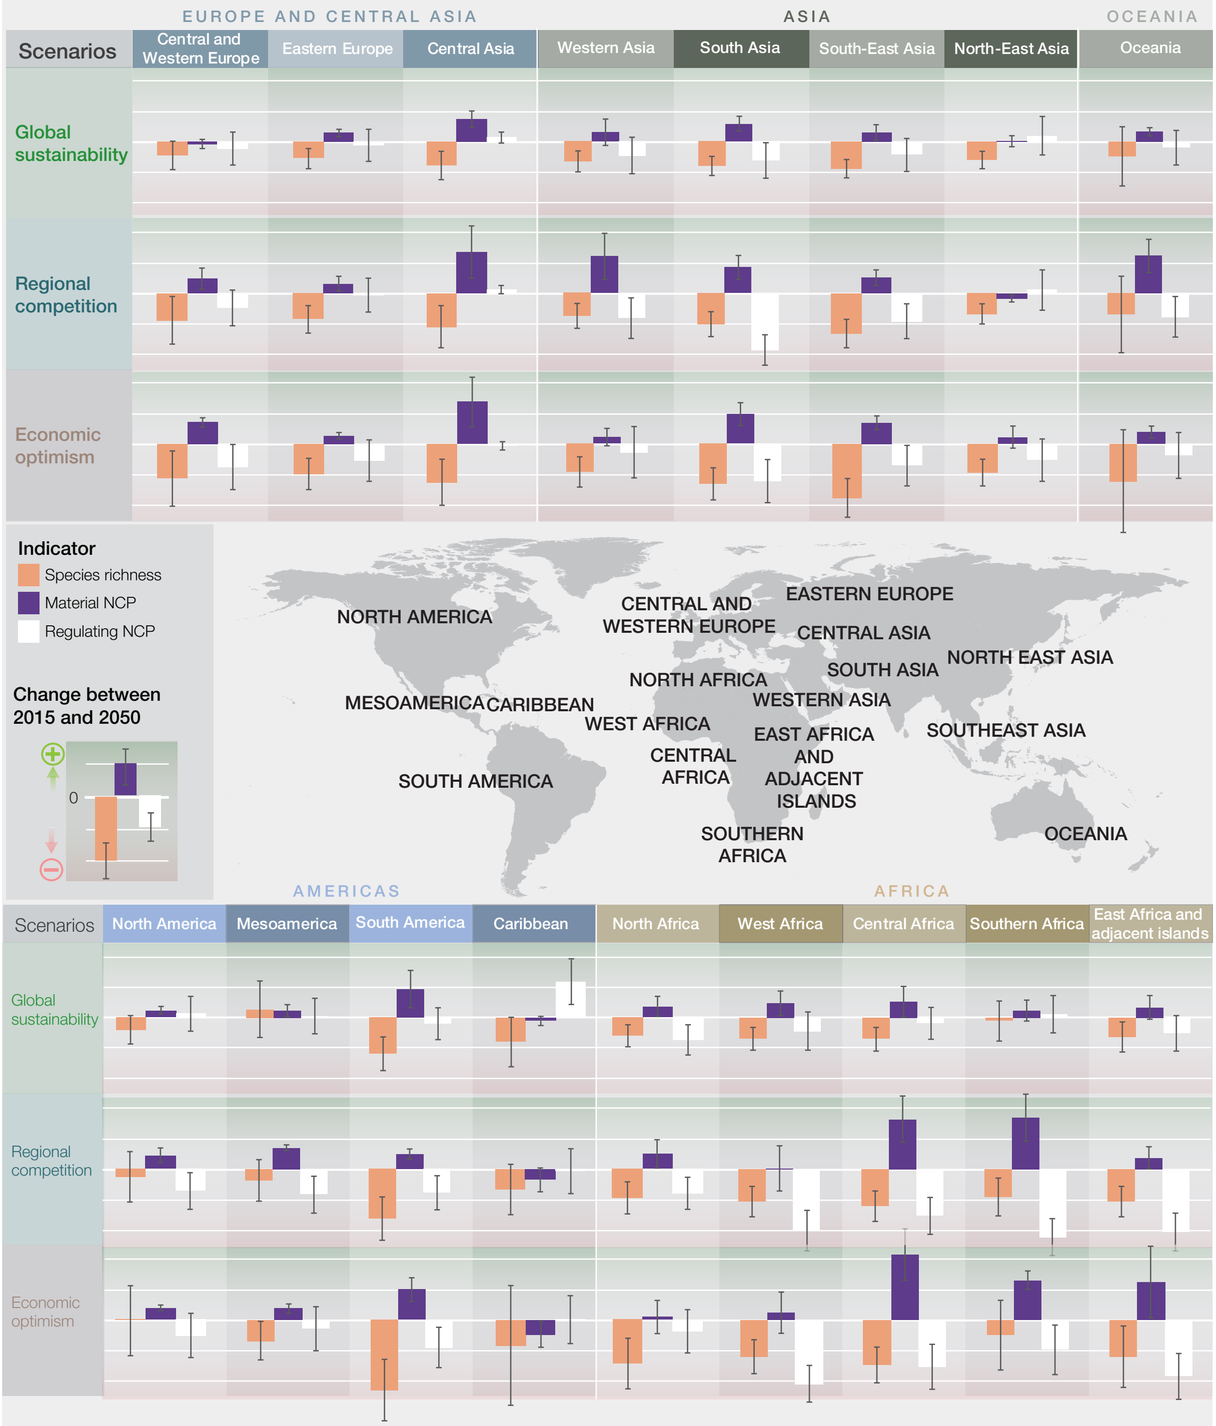

Figure SPM 8 **Projections of the impacts of land use and climate change on biodiversity and nature's material and regulating contributions to people between 2015 and 2050.**

This figure illustrates three main messages: i) the impacts on biodiversity and on nature's contributions to people (NCP) are the lowest in the "global sustainability" scenario in nearly all sub-regions, ii) regional differences in impacts are high in the regional competition and economic optimism scenario, and iii) material NCP increase the most in the regional competition and economic optimism scenarios, but this comes at the expense of biodiversity and regulating NCP. Projected impacts are based on a subset of the Shared Socioeconomic Pathway (SSP) scenarios and greenhouse gas emissions trajectories (RCP) developed in support of Intergovernmental Panel on Climate Change assessments. This figure does not cover the scenarios that include transformative change that are discussed in Chapter 5.

- The **"Global sustainability"** scenario combines proactive environmental policy and sustainable production and consumption with low greenhouse gas emissions (SSP1, RCP2.6; top rows in each panel);
- The **"Regional competition"** scenario combines strong trade and other barriers and a growing gap between rich and poor with high emissions (SSP3, RCP6.0; middle rows); and
- The **"Economic optimism"** scenario combines rapid economic growth and low environmental regulation with very high greenhouse emissions (SSP5, RCP8.5; bottom rows).

Multiple models were used with each of the scenarios to generate the first rigorous global-scale model comparison estimating the impact on biodiversity (change in species richness across a wide range of terrestrial plant and animal species at regional scales; orange bars), material NCP (food, feed, timber and bioenergy: purple bars) and regulating NCP (nitrogen retention, soil protection, crop pollination, crop pest control and ecosystem carbon storage and sequestration: white bars). The bars represent the normalized means of multiple models and the whiskers indicate the standard errors. The global means of percentage changes in individual indicators can be found in Figure 4.2.14.

28 **Climate change impacts also play a major role in regionally-differentiated projections of biodiversity and ecosystem functioning in both marine and terrestrial systems. Novel communities, where species will co-occur in historically unknown combinations, are expected to emerge (*established but incomplete*) {4.2.1.2, 4.2.4.1}** Substantial climate change-driven shifts of terrestrial biome boundaries, in particular in boreal, subpolar and polar regions and in (semi-) arid environments, are projected for the coming decades; a warmer, drier climate will reduce productivity in many places *(well established)* {4.2.4.1}. In contrast, rising atmospheric carbon dioxide concentrations can be beneficial for net primary productivity and can enhance woody vegetation cover, especially in semi-arid regions *(established but incomplete)* {4.2.4.1}. For marine systems, impacts are expected to be geographically variable, with many fish populations projected to move poleward due to ocean warming, meaning that local species extinctions are expected in the tropics *(well established)* {4.2.2.2.1}. However, that does not necessarily imply an increase in biodiversity in the polar seas, because of the rapid rate of sea ice retreat and the enhanced ocean acidification of cold waters *(established but incomplete)* {4.2.2.2.4}. Along coastlines, the upsurge in extreme climatic events, sea level rise and coastal development are expected to cause increased fragmentation and loss of habitats. Coral reefs are projected to undergo more frequent extreme warming events, with less recovery time in between, declining by a further 70–90 per cent at global warming of 1.5°C, and by more than 99 per cent at warming of 2°C, causing massive bleaching episodes with high coral mortality rates *(well established)* {4.2.2.2.2}.

D. Nature can be conserved, restored and used sustainably while simultaneously meeting other global societal goals through urgent and concerted efforts fostering transformative change.

29 **The Sustainable Development Goals and the 2050 Vision for Biodiversity cannot be achieved without transformative change, the conditions for which can be put in place now (*well established*) {2, 3, 5, 6.2} (Figure SPM.9)**. Increasing awareness of interconnectedness in the context of the environmental crisis and new norms regarding interactions between humans and nature would support that change *(well established)* {5.3, 5.4.3}. In the short term (before 2030), all decision makers could contribute to sustainability transformations, including through enhanced and improved implementation and enforcement of effective existing policy instruments and regulations, and the reform and removal of harmful existing policies and subsidies *(well established)*. Additional measures are necessary to enable transformative change over the long term (up to 2050) to address the indirect drivers that are the root causes of the deterioration of nature *(well established)*, including changes in social, economic and technological structures within and across nations {6.2, 6.3, 6.4} **(SPM Table.1)**.

30 **Sustainability transformations call for cross-sectoral thinking and approaches (Figure SPM.9). Sectoral policies and measures can be effective in particular contexts, but often fail to account for indirect, distant and cumulative impacts, which can have adverse effects, including the exacerbation of inequalities (*well established*).** Cross-sectoral

approaches, including landscape approaches, integrated watershed and coastal zone management, marine spatial planning, bioregional scale planning for energy, and new urban planning paradigms offer opportunities to reconcile multiple interests, values and forms of resource use, provided that these cross-sectoral approaches recognize trade-offs and uneven power relations between stakeholders *(established but incomplete)* {5.4.2, 5.4.3, 6.3, 6.4}.

31 **Transformative change is facilitated by innovative governance approaches that incorporate existing approaches, such as integrative, inclusive, informed and adaptive governance. While such approaches have been extensively practised and studied separately, it is increasingly recognized that together, they can contribute to transformative change (*established but incomplete*) {6.2}.** They help to address governance challenges that are common to many sectors and policy domains and create the conditions for implementing transformative change. Integrative approaches, such as mainstreaming across government sectors, are focused on the relationships between sectors and policies and help to ensure policy coherence and effectiveness *(well established)*. Inclusive approaches help to reflect a plurality of values and ensure equity *(established but incomplete)*, including through equitable sharing of benefits arising from their use and rights-based approaches *(established but incomplete)*. Informed governance entails novel strategies for knowledge production and co-production that are inclusive of diverse values and knowledge systems *(established but incomplete)*. Adaptive approaches, including learning from experience, monitoring and feedback loops, contribute to preparing for and managing the inevitable uncertainties and complexities associated with social and environmental changes *(established but incomplete)* {6.2, 5.4.2}.

32 **A summary of the evidence related to the components of pathways to sustainability suggests that there are five overarching types of management**

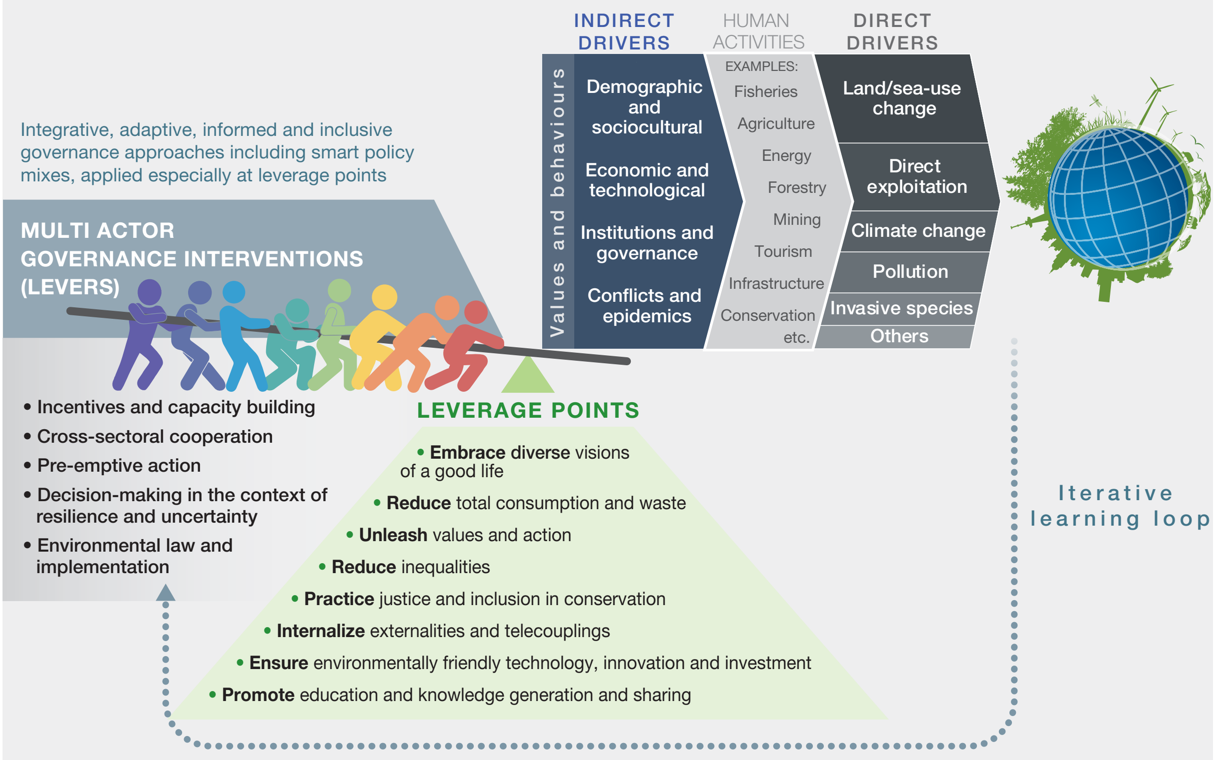

Figure SPM 9 **Transformative change in global sustainability pathways.**

Collaborative implementation of priority governance interventions (levers) targeting key points of intervention (leverage points) could enable transformative change from current trends towards more sustainable ones. Most levers can be applied at multiple leverage points by a range of actors, such as intergovernmental organizations, governments, non-governmental organizations, citizen and community groups, indigenous peoples and local communities, donor agencies, science and educational organizations, and the private sector, depending on the context. Implementing existing and new instruments through place-based governance interventions that are integrative, informed, inclusive and adaptive, using strategic policy mixes and learning from feedback, could enable global transformation.

interventions, or levers, and eight leverage points that are key for achieving transformative change (**Figure SPM.9**; D3 and D4 above) {5.4.1, 5.4.2}. The notion of levers and leverage points recognizes that complex global systems cannot be managed simply, but that in certain cases, specific interventions can be mutually reinforcing and can generate larger-scale changes towards achieving shared goals *(well established)* **(Table SPM.1)**. For example, changes in laws and policies can enable and underpin changes in resource management and consumption, and in turn, changes in individual and collective behaviour and habits can facilitate the implementation of policies and laws {5.4.3}.

33 **Changes towards sustainable production and consumption and towards reducing and transforming residues and waste, particularly changes in consumption among the affluent, is recognized by some individuals and communities worldwide as central to sustainable development and reducing inequalities. While actual reductions have been limited, actions already being taken at different levels can be improved, coordinated and scaled up *(well established).*** Those include introducing and improving standards, systems and relevant regulations aimed at internalizing the external costs of production, extraction and consumption (such as pricing wasteful or polluting practices, including through penalties); promoting resource efficiency and circular and other economic models; voluntary environmental and social certification of market chains; and incentives that promote sustainable practices and innovation. Importantly, they also involve a change in the definition of what a good quality of life entails – decoupling the idea of a good and meaningful life from ever-increasing material consumption. All those approaches are more effective when they are mutually reinforcing. Actions that help to voluntarily unleash existing social values of responsibility in the form of individual, collective and organizational actions towards sustainability can have a powerful and lasting effect in shifting behaviour and cultivating stewardship as a normal social practice *(established but incomplete)* {5.4.1.2, 5.4.1.3, 6.4.2, 6.4.3}.

34 **Expanding and effectively managing the current network of protected areas, including terrestrial, freshwater and marine areas, is important for safeguarding biodiversity (*well established*), particularly in the context of climate change. Conservation outcomes also depend on adaptive governance, strong societal engagement, effective and equitable benefit-sharing mechanisms, sustained funding, and monitoring and enforcement of rules (*well established*) {6.2, 5.4.2}.** National Governments play a central role in supporting primary research, effective conservation and the sustainable use of multi-functional landscapes and seascapes. This entails planning ecologically representative networks of interconnected protected areas to cover key biodiversity areas and managing trade-offs between societal objectives that represent diverse worldviews and multiple values of nature *(established but incomplete)* {6.3.2.3, 6.3.3.3}. Safeguarding protected areas into the future also entails enhancing monitoring and enforcement systems, managing biodiversity-rich land and sea beyond protected areas, addressing property rights conflicts and protecting environmental legal frameworks against the pressure of powerful interest groups. In many areas, conservation depends on building capacity and enhancing stakeholder collaboration, involving non-profit groups as well as indigenous peoples and local communities to establish and manage marine protected areas and marine protected area networks, and proactively using instruments such as landscape-scale and seascape-scale participatory scenarios and spatial planning, including transboundary conservation planning *(well established)* {5.3.2.3, 6.3.2.3, 6.3.3.3}. Implementation beyond protected areas includes combating wildlife and timber trafficking through effective enforcement and ensuring the legality and sustainability of trade in wildlife. Such actions include prioritizing the prosecution of wildlife trafficking in criminal justice systems, using community-based social marketing to reduce demand and implementing strong measures to combat corruption at all levels *(established but incomplete)* {6.3.2.3}.

35 **Integrated landscape governance entails a mix of policies and instruments that together ensure nature conservation, ecological restoration and sustainable use, sustainable production (including of food, materials and energy), and sustainable forest management and infrastructure planning, and that address the major drivers of biodiversity loss and nature deterioration (*well established*) {6.3.2, 6.3.6}.** Policy mixes that are harmonized across sectors, levels of governance and jurisdictions can account for ecological and social differences across and beyond the landscape, build on existing forms of knowledge and governance and address trade-offs between tangible and non-tangible benefits in a transparent and equitable manner *(established but incomplete)*. Sustainable landscape management can be better achieved through multifunctional, multi-use, multi-stakeholder and community-based approaches *(well established)*, using a combination of measures and practices, including: (a) well-managed and connected protected areas and other effective area-based conservation measures; (b) reduced impact logging, forest certification, payment for ecosystem services, among other instruments, and reduced emissions from deforestation and forest degradation; (c) support for ecological restoration; (d) effective monitoring, including public access and participation as appropriate; (e) addressing illegal activities; (f) the effective implementation of multilateral environmental agreements and other relevant international agreements by

their parties; and (g) promoting sustainable, biodiversity-based food systems *(well established)* {6.3.2.1, 6.3.2.3, 6.3.2, 6.3.2.4}.

36 **Feeding the world in a sustainable manner, especially in the context of climate change and population growth, entails food systems that ensure adaptive capacity, minimize environmental impacts, eliminate hunger, and contribute to human health and animal welfare *(established but incomplete)* {5.3.2.1, 6.3.2.1}. Pathways to sustainable food systems entail land-use planning and sustainable management of both the supply/producer and the demand/consumer sides of food systems (*well established*) {5.3.2.1, 6.3.2.1, 6.4}.** Options for sustainable agricultural production are available and continue to be developed, with some having more impacts on biodiversity and ecosystem functions than others {6.3.2.1}. These options include integrated pest and nutrient management, organic agriculture, agroecological practices, soil and water conservation practices, conservation agriculture, agroforestry, silvopastoral systems, irrigation management, small or patch systems and practices to improve animal welfare. These practices could be enhanced through well-structured regulations, incentives and subsidies, the removal of distorting subsidies {2.3.5.2, 5.3.2.1, 5.4.2.1, 6.3.2}, and – at landscape scales – by integrated landscape planning and watershed management. Ensuring the adaptive capacity of food production entails the use of measures that conserve the diversity of genes, varieties, cultivars, breeds, landraces and species, which also contributes to diversified, healthy and culturally-relevant nutrition. Some incentives and regulations may contribute to positive changes at both the production and consumption ends of supply chains, such as the creation, improvement and implementation of voluntary standards, certification and supply-chain agreements (e.g., the Soy Moratorium) and the reduction of harmful subsidies. Regulatory mechanisms could also address the risks of co-option and lobbying, where commercial or sectoral interests may work to maintain high levels of demand, monopolies and continued use of pesticides and chemical inputs {5.3.2.1}. Non-regulatory alternatives are also important, and potentially include technical assistance – especially for small-holders – and appropriate economic incentive programs, for example, some payment for ecosystem services programmes and other non-monetary instruments {5.4.2.1}. Options that address and engage other actors in food systems (including the public sector, civil society, consumers and grassroots movements) include participatory on-farm research, the promotion of low-impact and healthy diets and the localization of food systems. Such options could help reduce food waste, overconsumption, and the demand for animal products that are produced unsustainably, which could have synergistic benefits for human health *(established but incomplete)* {5.3.2.1, 6.3.2.1}.

37 **Ensuring sustainable food production from the oceans while protecting biodiversity entails policy action to apply sustainable ecosystem approaches to fisheries management; spatial planning (including the implementation and expansion of marine protected areas); and more broadly, policy action to address drivers such as climate change and pollution (*well established*) {5.3.2.5, 6.3.3}.** Scenarios show that the pathways to sustainable fisheries entail conserving, restoring and sustainably using marine ecosystems, rebuilding overfished stocks (including through targeted limits on catches or fishing efforts and moratoria), reducing pollution (including plastics), managing destructive extractive activities, eliminating harmful subsidies and illegal, unreported and unregulated fishing, adapting fisheries management to climate change impacts and reducing the environmental impact of aquaculture *(well established)* {4, 5.3.2.5, 6.3.3.3.2}. Marine protected areas have demonstrated success in both biodiversity conservation and improved local quality of life when managed effectively and can be further expanded through larger or more interconnected protected areas or new protected areas in currently underrepresented regions and key biodiversity areas *(established but incomplete)* {5.3.2.5; 6.3.3.3.1}. Due to major pressures on coasts (including from development, land reclamation and water pollution), implementing marine conservation initiatives, such as integrated coastal planning, outside of protected areas is important for biodiversity conservation and sustainable use *(well established)* {6.3.3.3}. Other measures to expand multi-sectoral cooperation on coastal management include corporate social responsibility measures, standards for building and construction, and eco-labelling *(well established)* {6.3.3.3.2, 6.3.3.3.4}. Additional tools could include both non-market and market-based economic instruments for financing conservation, including for example payment for ecosystem services, biodiversity offset schemes, blue-carbon sequestration, cap-and-trade programmes, green bonds and trust funds and new legal instruments, such as the proposed international, legally binding instrument on the conservation and sustainable use of marine biological diversity in areas beyond national jurisdiction under the United Nations Convention on the Law of the Sea *(established but incomplete)* {6.3.3.2, 6.3.3.1.3, 5.4.2.1, 5.4.1.7}.

38 **Sustaining freshwater in the context of climate change, rising demand for water extraction and increased levels of pollution involves both cross-sectoral and sector-specific interventions that improve water-use efficiency, increase storage, reduce sources of pollution, improve water quality, minimize disruption and foster the restoration of natural habitats and flow regimes (*well established*) {6.3.4}.** Promising interventions include practising integrated water resource management and landscape planning across

scales; protecting wetland biodiversity areas; guiding and limiting the expansion of unsustainable agriculture and mining; slowing and reversing the de-vegetation of catchments; and mainstreaming practices that reduce erosion, sedimentation, and pollution run-off and minimize the negative impact of dams *(well established)* {6.3.4.6}. Sector-specific interventions include improved water-use efficiency techniques (including in agriculture, mining and energy), decentralized rainwater collection (for example, household-based), integrated management of surface and groundwater (e.g., "conjunctive use"), locally-developed water conservation techniques, and water pricing and incentive programmes (such as water accounts and payment for ecosystem services programmes) {6.3.4.2, 6.3.4.4}. With regard to watershed payment for ecosystem services programmes, their effectiveness and efficiency can be enhanced by acknowledging multiple values in their design, implementation and evaluation and setting up impact evaluation systems *(established but incomplete)* {6.3.4.4}. Investment in infrastructure, including in green infrastructure, is important, especially in developing countries, but it can be undertaken in a way that takes into account ecological functions and the careful blending of built and natural infrastructure {5.3.2.4, 6.3.4.5}.

39 **Meeting the Sustainable Development Goals in cities and making cities resilient to climate change entails solutions that are sensitive to social, economic and ecological contexts. Integrated city-specific and landscape-level planning, nature-based solutions and built infrastructure, and responsible production and consumption can all contribute to sustainable and equitable cities and make a significant contribution to the overall climate change adaptation and mitigation effort.** Urban planning approaches to promote sustainability include encouraging compact communities, designing nature-sensitive road networks and creating low-impact infrastructure and transportation systems (from an emissions and land-use perspective), including active, public and shared transport {5.3.2.6, 6.3.5}. However, given that most urban growth between now and 2030 will take place in the Global South, major sustainability challenges include creatively and inclusively addressing the lack of basic infrastructure (water, sanitation and mobility), the absence of spatial planning, and the limited governance capacity and financing mechanisms. Those challenges also offer opportunities for locally-developed innovation and experimentation, which will create new economic opportunities. A combination of bottom-up and city-level efforts through public, private, community and Government partnerships, can be effective in promoting low-cost and locally-adapted solutions to maintaining and restoring biodiversity and ecosystem functions and services. Nature-based options include combining grey and green infrastructure (such as wetland and watershed restoration and green roofs), enhancing green spaces through restoration and expansion, promoting urban gardens, maintaining and designing for ecological connectivity, and promoting accessibility for all (with benefits for human health). Additional solutions include disseminating new, low-cost technologies for decentralized wastewater treatment and energy production and creating incentives to reduce over-consumption {6.3.5}. Integrating cross-sectoral planning at the local, landscape and regional levels is important, as is involving diverse stakeholders *(well established)*. Particularly important at the regional scale are policies and programmes that promote sustainability-minded collective action {5.4.1.3}, protect watersheds beyond city jurisdictions and ensure the connectivity of ecosystems and habitats (e.g., through green belts). At the regional scale, cross-sectoral approaches to mitigating the impact of infrastructure and energy projects entail support for comprehensive environmental impact assessments and strategic environmental assessments of local and regional cumulative impacts {6.3.6.4, 6.3.6.6}.

40 **Decision makers have a range of options and tools for improving the sustainability of economic and financial systems *(well established)* {6.4}. Achieving a sustainable economy involves making fundamental reforms to economic and financial systems and tackling poverty and inequality as vital parts of sustainability (*well established*) {6.4}.** Governments could reform subsidies and taxes to support nature and its contributions to people, removing perverse incentives and instead promoting diverse instruments such as payments linked to social and environmental metrics, as appropriate *(established but incomplete)* {6.4.1}. At the international level, options for reacting to the challenges generated by the displacement of the impacts of unsustainable consumption and production on nature include both rethinking established instruments and developing new instruments to account for long-distance impacts. Trade agreements and derivatives markets could be reformed to promote equity and prevent the deterioration of nature, although there are uncertainties associated with implementation *(established but incomplete)* {6.4.4}. Alternative models and measures of economic welfare (such as inclusive wealth accounting, natural capital accounting and degrowth models) are increasingly considered as possible approaches to balancing economic growth and the conservation of nature and its contributions and to recognizing trade-offs, the pluralism of values, and long-term goals *(established but incomplete)* {6.4.5}. Structural changes to economies are also key to shifting action over long timescales. Such changes include technological and social innovation regimes and investment frameworks that internalize environmental impacts, such as the externalities of economic activities, including by addressing environmental impacts in socially just and appropriate ways *(well established)* {5.4.1.7}. Although such market-based policy instruments as payments for ecosystem services, voluntary certification and

biodiversity offsetting have increased in use, their effectiveness is mixed, and they are often contested; thus, they should be carefully designed and applied to avoid perverse effects in context *(established but incomplete)* {5.4.2.1, 6.3.2.2, 6.3.2.5, 6.3.6.3}. The widespread internalization of environmental impacts, including externalities associated with long-distance trade, is considered both an outcome and a component of national and global sustainable economies *(well established)* {5.4.1.6, 6.4}.

Table SPM 1 **Approaches for sustainability and possible actions and pathways for achieving them.**

The appropriateness and relevance of different approaches varies according to place, system, decision-making process and scale. The list of actions and pathways in the following table is illustrative rather than exhaustive and uses examples from the assessment report.

Approaches for sustainability	Possible actions and pathways to achieve transformative change Key actors: (IG=intergovernmental organizations, G=Governments, NGOs =non-governmental organizations, CG=citizen and community groups, IPLC = indigenous peoples and local communities, D=donor agencies, SO= science and educational organizations, P=private sector)
Enabling integrative governance to ensure policy coherence and effectiveness	• Implementing **cross-sectoral approaches** that consider linkages and interconnections between sectoral policies and actions (e.g., IG, G, D, IPLC) {6.2} {D1}. • **Mainstreaming biodiversity** within and across different sectors (e.g., agriculture, forestry, fisheries, mining, tourism) (e.g., IG, G, NGO, IPLC, CG, P, D) {6.2, 6.3.5.2} {D5}. • **Encouraging integrated planning and management for sustainability at the landscape and seascape levels** (e.g., IG, G, D) {6.3.2} {D5}. • **Incorporating environmental and socioeconomic impacts**, including externalities, into public and private decision-making (e.g., IG, G, P) {5.4.1.6} {B5}. • **Improving existing policy instruments** and using them **strategically and synergistically** in smart policy mixes (e.g., IG, G) {6.2, 6.3.2, 6.3.3.3.1, 6.3.4.6, 6.3.5.1, 6.3.6.1} {D4}.
Promoting inclusive governance approaches through stakeholder engagement and the inclusion of indigenous peoples and local communities to ensure equity and participation	• **Recognizing and enabling the expression of different value systems and diverse interests** while formulating and implementing policies and actions (e.g., IG, G, IPLCs, CG, NGO, SO, D) {6.2} {B5, D5}. • **Enabling the inclusion and participation** of indigenous peoples and local communities, and women and girls in environmental governance and **recognizing and respecting the knowledge, innovations, and practices, institutions and values** of indigenous peoples and local communities, in accordance with national legislation (e.g., G, IPLC, P) {6.2, 6.2.4.4} {D5}. • **Facilitating national recognition for land tenure, access and resource rights** in accordance with national legislation, and the application of **free, prior and informed consent and fair and equitable benefit-sharing arising from their use** (e.g., G, IPLC, P) {D5}. • Improving **collaboration and participation among** indigenous peoples and local communities, other relevant stakeholders, policymakers and scientists to generate novel ways of conceptualizing and achieving transformative change towards sustainability (e.g., G, IG, D, IPLC, CG, SO) {D5}.
Practicing informed governance for nature and nature's contributions to people	• **Improving the documentation of nature** (e.g., biodiversity inventory and other inventories) **and the assessment of the multiple values of nature, including the valuation of natural capital** by both private and public entities (e.g., SO, D, G, IG, P) {6.2} {D2}. • **Improving the monitoring and enforcement** of existing laws and policies through **better documentation and information-sharing** and **regular, informed and adaptive readjustments** to ensure transparent and enhanced results as appropriate (e.g., IG, G, IPLC, P) {D2}. • Advancing knowledge co-production and **including and recognizing different types of knowledge**, including indigenous and local knowledge and education, that enhances the legitimacy and effectiveness of environmental policies (e.g., SO, IG, G, D) {B6, D3}.
Promoting adaptive governance and management	• **Enabling locally tailored choices** about conservation, restoration, sustainable use and development connectivity that account for uncertainty in environmental conditions and scenarios of climate change (e.g., G, IPLC, CG, P) {D3}. • **Promoting public access to relevant information as appropriate** in decision-making and responsiveness to assessments by improving monitoring, including setting goals and objectives with multiple relevant stakeholders, who often have competing interests (e.g., IG, G). • **Promoting awareness-raising activities** around the principles of adaptive management, including through using short, medium and long-term goals that are regularly reassessed towards international targets (e.g., IG, G, SO, CG, D) {D4}. • Piloting and testing **well-designed policy innovations** that experiment with scales and models (e.g., G, D, SO, CG, IPLC) {D4}. • Increasing the **effectiveness of current and future international biodiversity targets and goals** (such as those of the post-2020 global biodiversity framework and of the Sustainable Development Goals), (e.g., IG, G, D) {6.2, 6.4}.

Approaches for sustainability	Possible actions and pathways to achieve transformative change Key actors: (IG=intergovernmental organizations, G=Governments, NGOs =non-governmental organizations, CG=citizen and community groups, IPLC = indigenous peoples and local communities, D=donor agencies, SO= science and educational organizations, P=private sector)
Managing sustainable and multifunctional landscapes and seascapes and some of the actions they may entail	
Producing and consuming food sustainably	• **Promoting sustainable agricultural practices**, including good agricultural practices, agroecology, among others, multifunctional landscape planning and cross-sectoral integrated management {6.3.2}. • **Sustainable use of genetic resources in agriculture,** including by conserving gene diversity, varieties, cultivars, breeds, landraces and species (e.g., SO, IPLC, CG) {6.3.2.1} {A6}. • **Promoting the use of biodiversity-friendly management practices** in crop and livestock production, forestry, fisheries and aquaculture, including, where relevant, the use of traditional management practices associated with indigenous peoples and local communities {6.3.2.1} {D6}. • **Promoting areas of natural or semi-natural habitat** within and around production systems, including those that are intensively managed, and restoring or reconnecting damaged or fragmented habitats where necessary {6.3.2.1} {D6}. • Improving **food market transparency** (e.g., traceability of biodiversity impacts, transparency in supply chains) through tools such as labelling and sustainability certification. • **Improving equity in food distribution and in the localization of food systems**, where appropriate and where beneficial to nature or nature's contributions to people (NCP). • **Reducing food waste from production to consumption.** • Promoting **sustainable and healthy diets** {6.3.2.1} {D6}.
Integrating multiple uses for sustainable forests	• Promoting **multifunctional, multi-use and multi-stakeholder approaches and improving community-based approaches** to forest governance and management to achieve sustainable forest management (e.g., IG, G, CG, IPLC, D, SO, P) {6.3.2.2} {A4}. • Supporting the **reforestation and ecological restoration** of degraded forest habitats with appropriate species, giving priority to native species (e.g., G, IPLC, CG, D, SO) {6.3.2.2} {A4}. • **Promoting and strengthening community-based management and governance, including customary institutions and management systems, and co-management regimes involving** indigenous peoples and local communities (e.g., IG, G, CG, IPLC, D, SO, P) {6.3.2.2} {D5}. • **Reducing the negative impact of** unsustainable **logging** by improving and implementing sustainable forest management, and **addressing illegal logging** (e.g., IG, G, NGO, P) {6.3.2.2} {D1}. • **Increasing efficiency in forest product use**, including incentives for adding value to forest products (such as sustainability labelling or public procurement policies), as well as promoting intensive production in well-managed forests so as to reduce pressures elsewhere (e.g., P, D, NGO) {6.3.2.2} {B1}.
Conserving, effectively managing and sustainably using terrestrial landscapes	• **Supporting, expanding and promoting effectively managed and ecologically representative networks** of well-connected protected areas and other multifunctional conservation areas, such as other effective area-based conservation measures (e.g., IG, G, IPLC, CG, D) {3.2.1, 6.3.2.3} {C1, D7}. • **Using extensive, proactive and participatory landscape-scale spatial planning** to prioritize land uses that balance and further safeguard nature and **to protect and manage key biodiversity areas** and other important sites for present and future biodiversity (e.g., IG, G, D) {B1, D7}. • Managing and restoring biodiversity beyond protected areas, (e.g., IG, G, CG, IPLC, P, NGO, D) {B1}. • **Developing robust and inclusive decision-making processes** that facilitate the positive contributions of indigenous peoples and local communities to sustainability by incorporating locally-attuned management systems and indigenous and local knowledge {B6, D5}. • **Improving and expanding the levels of financial support** for conservation and sustainable use through a variety of innovative options, including through partnerships with the private sector {6.3.2.5} {D5, D7, D10}. • **Prioritizing land-based adaptation and mitigation measures that do not have negative impacts on biodiversity** (e.g., reducing deforestation, restoring land and ecosystems, improving the management of agricultural systems such as soil carbon, and preventing the degradation of wetlands and peatlands) {D8}. • **Monitoring the effectiveness and impacts of protected areas** and other effective area-based conservation measures.
Promoting sustainable governance and management of seascapes, oceans and marine systems	• Promoting shared and **integrated ocean governance, including for biodiversity, beyond national jurisdictions** (e.g., IG, G, NGO, P, SO, D) {6.3.3.2} {D7}. • **Expanding, connecting and effectively managing marine protected area networks** (e.g., IG, G, IPLC, CG {5.3.2.3} {D7}, including protecting and managing priority marine key biodiversity areas and other important sites for present and future biodiversity, and **increasing protection and connectivity.** • **Promoting the conservation and/or restoration of marine ecosystems** through rebuilding overfished stocks; preventing, deterring and eliminating illegal, unreported and unregulated fishing; encouraging ecosystem-based fisheries management; and controlling pollution through the removal of derelict gear and through addressing plastics pollution (e.g., IG, G, P, IPLC, CG, SO, D) {B1, D7}. • **Promoting ecological restoration, remediation and the multifunctionality of coastal structures**, including through marine spatial planning (e.g., IG, G, NGO, P, CG, IPLC, SO, D) {6.3.3.3.1} {B1, D7}. • Integrating **ecological functionality concerns into the planning phase of coastal construction** (e.g., IG, G, NGO, P, CG, IPLC, SO, D) {6.3.3.3.1} {B1, D7}. • **Expanding multi-sectoral cooperation** by increasing and improving corporate social responsibility measures and regulation in building and construction standards, and eco-labelling and best practices (e.g., IG, G, NGO, P, CG, IPLC, SO, D) {6.3.3.3.1} {B1, D7}.

Table SPM 1 *(continued)*

Approaches for sustainability	Possible actions and pathways to achieve transformative change Key actors: (IG=intergovernmental organizations, G=Governments, NGOs =non-governmental organizations, CG=citizen and community groups, IPLC = indigenous peoples and local communities, D=donor agencies, SO= science and educational organizations, P=private sector)
Promoting sustainable governance and management of seascapes, oceans and marine systems	• **Encouraging effective fishery reform strategies** through incentives with positive impacts on biodiversity and through the removal of environmentally harmful subsidies (e.g., IG, G) {6.3.3.2} {D7}. • **Reducing the environmental impacts of aquaculture** by voluntary certification and by using best practices in fisheries and aquaculture production methods (e.g., G, IPLC, NGO, P) {6.3.3.3.2, 6.3.3.3.5} {B1, D7}. • **Reducing point and nonpoint source pollution**, including by managing marine microplastic and macroplastic pollution through effective waste management, incentives and innovation (e.g., G, P, NGO) {6.3.3.3.1} {B1, D7}. • **Increasing ocean conservation funding** (e.g., G, D, P) {6.3.3.1.3} {D7}.
Improving freshwater management, protection and connectivity	• **Integrating water resource management and landscape planning**, including through increased protection and connectivity of freshwater ecosystems, improving transboundary water cooperation and management, addressing the impacts of fragmentation caused by dams and diversions, and incorporating regional analyses of the water cycle (e.g., IG, G, IPLC, CG, NGO, D, SO, P) {6.3.4.6, 6.3.4.7} {B1}. • **Supporting inclusive water governance,** e.g., through developing and implementing invasive alien species management with relevant stakeholders (e.g., IG, G, IPLC, CG, NGO, D, SO, P) {6.3.4.3} {D4}. • **Supporting co-management regimes for collaborative water management** and **to foster equity** between water users (while maintaining a minimum ecological flow for the aquatic ecosystems), and engaging stakeholders and using transparency to minimize environmental, economic and social conflicts {D4}. • Mainstreaming practices that **reduce soil erosion, sedimentation and pollution run-off** (e.g., G, CG, P) {6.3.4.1}. • **Reducing the fragmentation of freshwater policies** by coordinating international, national and local regulatory frameworks (e.g., G, SO) {6.3.4.7, 6.3.4.2}. • **Increasing water storage** by facilitating groundwater recharge, wetlands protection and restoration, alternative storage techniques and restrictions on groundwater abstraction. (e.g., G, CG, IPLC, P, D) {6.3.4.2} {B1, B3}. • **Promoting investment in water projects** with clear sustainability criteria (e.g., G, P, D, SO) {6.3.4.5} {B1, B3}.
Building sustainable cities that address critical needs while conserving nature, restoring biodiversity, maintaining and enhancing ecosystem services	• Engaging **sustainable urban planning** (e.g., G, CG, IPLC, NGO, P) {6.3.5.1} {D9}. • **Encouraging densification for compact communities**, including through brownfield development and other strategies {6.3.5.3}. • **Including biodiversity protection, biodiversity offsetting, river basin protection, and ecological restoration in regional planning** {6.3.5.1}. • **Safeguarding urban key biodiversity areas** and ensuring that they do not become isolated through incompatible uses of surrounding land {6.3.5.2, SM 6.4.2}. • **Promoting biodiversity mainstreaming through stakeholder engagement and integrative planning** (e.g., G, NGO, CG, IPLC) {6.3.5.3}. • **Encouraging alternative business models and incentives for urban conservation** {6.3.2.1}. • **Promoting sustainable production and consumption** {6.3.6.4}. • **Promoting nature-based solutions** (e.g., G, NGO, SO, P) {6.3.5.2} {D8, D9}. • **Promoting, developing, safeguarding or retrofitting green and blue infrastructure** (for water management) while improving grey (hard) infrastructure to address biodiversity outcomes, {6.3.5.2}. • **Promoting ecosystem-based adaptation within communities** {3.7, 5.4.2.2}. • Maintaining and designing for **ecological connectivity within urban spaces**, particularly with native species {6.3.5.2, SM 6.4.1}. • **Increasing urban green spaces and improving access to them** {6.3.2}. • **Increasing access to urban services for low-income communities**, with priorities for sustainable water management, integrated sustainable solid waste management and sewage systems, and safe and secure shelter and transport (e.g., G, NGO) {6.3.5.4} {D9}.
Promoting sustainable energy and infrastructure projects and production	• Developing **sustainable strategies, voluntary standards and guidelines** for sustainable renewable energy and bioenergy projects (e.g., G, SO, P) {6.3.6} {D8}. • Strengthening and promoting **biodiversity-inclusive environmental impact assessments**, laws and guidelines {6.3.6.2} {B1}. • **Mitigating environmental and social impacts** where possible and **promoting innovative financing and restoration** when necessary (e.g., G, P, NGO, D) {6.3.6.3} {B1}, including by redesigning **incentive programmes and policies** to promote bioenergy systems that optimize trade-offs between biodiversity loss and benefits (e.g., through life cycle analysis) {D8}. • **Supporting community-based management and decentralized** sustainable energy production (e.g., G, CG, IPLC, D) {6.3.6.4, 6.3.6.5} {D9}. • **Reducing energy demands** so as to reduce the demand for biodiversity-impacting infrastructure (e.g., through energy efficiency, new clean energy and reducing unsustainable consumption) (e.g., G, P) {B1}.

Approaches for sustainability	Possible actions and pathways to achieve transformative change Key actors: (IG=intergovernmental organizations, G=Governments, NGOs =non-governmental organizations, CG=citizen and community groups, IPLC = indigenous peoples and local communities, D=donor agencies, SO= science and educational organizations, P=private sector)
Improving the sustainability of economic and financial systems	• **Developing and promoting incentive structures** to protect biodiversity (e.g., removing harmful incentives) (e.g., IG, G) {6.4} {D10}. • Promoting **sustainable production and consumption**, such as through: sustainable sourcing, resource efficiency and reduced production **impacts**, circular and other economic models, corporate social responsibility, life-cycle assessments that include biodiversity, trade agreements and public procurement policies (e.g., G, CA, NGO, SO) {6.4.3, 6.3.2.1} {D10}. • **Exploring alternative methods of economic accounting** such as natural capital accounting and Material and Energy Flow Accounting, among others (e.g., IG, G, SO) {6.4.5} {D10}. • **Encouraging policies that combine poverty reduction** with measures to increase the provision of nature's contributions and the conservation and sustainable use of nature (e.g., IG, G, D) {3.2.1} {C2}. • **Improving market-based instruments**, such as payment for ecosystem services, voluntary certification and biodiversity offsetting, to address challenges such as equity and effectiveness (e.g., G, P, NGO, IPLC, CG, SO) {B1}. • **Reducing consumption** (e.g., encouraging consumer information to reduce overconsumption and waste, using public policies and regulations and internalizing environmental impacts) (e.g., G, P, NGO) {B4, C2}. • **Creating and improving supply-chain models** that reduce the impact on nature {D3}.

APPENDICES

APPENDIX 1
Conceptual framework and definitions

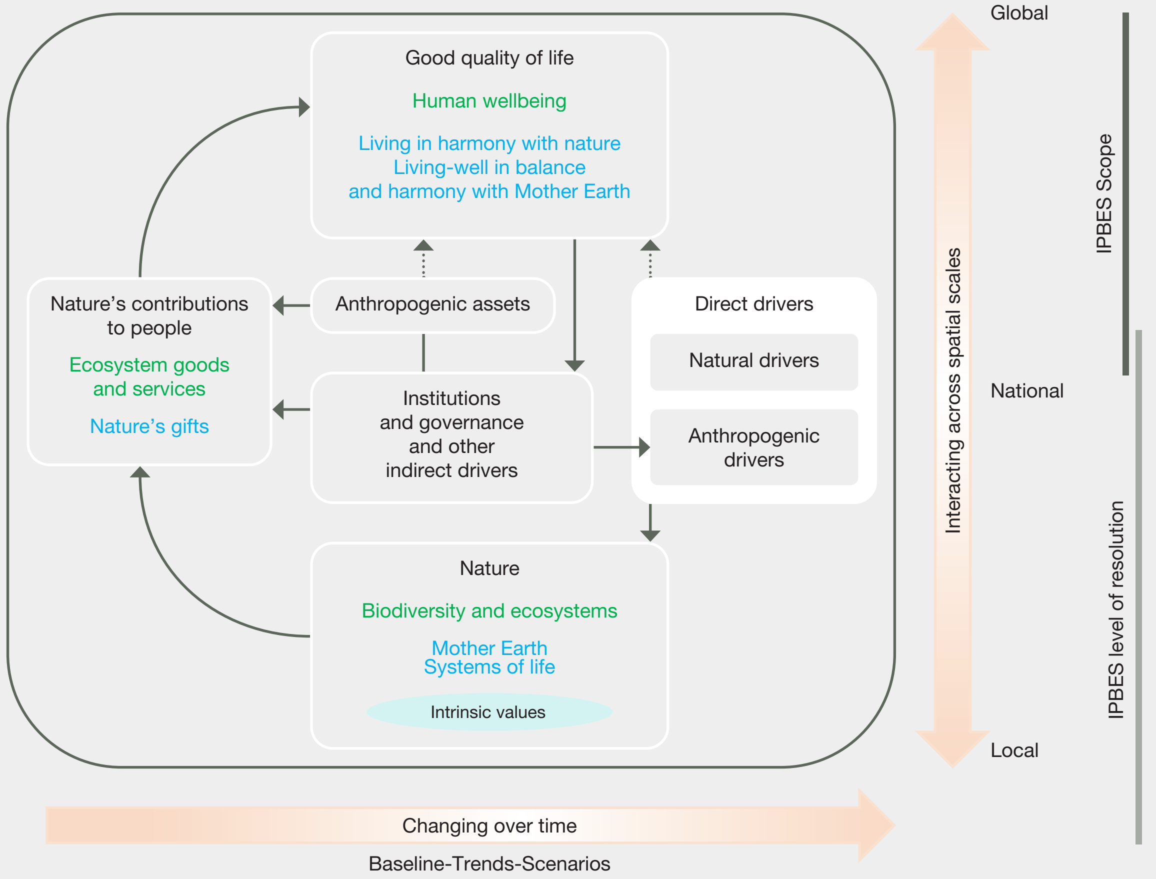

Figure SPM A 1 **The IPBES conceptual framework. Source: Díaz *et al.* (2015).**

Figure SPM A1. The IPBES Conceptual Framework is a highly simplified model of the complex interactions between the natural world and human societies. The model identifies the main elements (boxes within the main panel outlined in grey), together with their interactions (arrows in the main panel), that are most relevant to the Platform's goal. "Nature", "nature's contributions to people" and "good quality of life" (indicated as black headlines and defined in each corresponding box) are inclusive categories that were identified as meaningful and relevant to all stakeholders involved in IPBES during a participatory process, including various disciplines of the natural and social sciences and the humanities, and other knowledge systems, such as those of indigenous peoples and local communities. Text in green denotes scientific concepts, and text in blue denotes concepts originating in other knowledge systems. The solid arrows in the main panel denote influence between elements, and dotted arrows denote links that are acknowledged as important, but that are not the main focus of the Platform. The thick coloured arrows below and to the right of the central panel indicate the scales of time and space, respectively. This conceptual framework was accepted by the Plenary in decision IPBES-2/4, and the Plenary took note of an update presented in IPBES/5/INF/24 and in decision IPBES-5/1. Further details and examples of the concepts defined in the box can be found in the glossary and in Chapter 1.

Nature, in the context of the Platform, refers to the natural world, with an emphasis on biodiversity. Within the context of science, it includes categories such as biodiversity, ecosystems, ecosystem functioning, evolution, the biosphere, humankind's shared evolutionary heritage, and biocultural diversity. Within the context of other knowledge systems, it includes categories such as Mother Earth and systems of life. Other components of nature, such as deep aquifers, mineral and fossil reserves, and wind, solar, geothermal and wave power, are not the focus of the Platform. Nature contributes to societies through the provision of contributions to people.

Anthropogenic assets refers to built-up infrastructure, health facilities, knowledge (including indigenous and local knowledge systems and technical or scientific knowledge, as well as formal and non-formal education), technology (both physical objects and procedures), and financial assets, among others. Anthropogenic assets have been highlighted to emphasize that a good life is achieved by a co-production of benefits between nature and societies.

Nature's contributions to people refers to all the contributions that humanity obtains from nature. Ecosystem goods and services, considered separately or in bundles, are included in this category. Within other knowledge systems, nature's gifts and similar concepts refer to the benefits of nature from which people derive good quality of life. Aspects of nature that can be negative to people (detriments), such as pests, pathogens or predators, are also included in this broad category.

Nature's regulating contributions to people refers to functional and structural aspects of organisms and ecosystems that modify the environmental conditions experienced by people, and/or sustain and/or regulate the generation of material and non-material contributions. For example, these contributions include water purification, climate regulation and the regulation of soil erosion.

Nature's material contributions to people refers to substances, objects or other material elements from nature that sustain people's physical existence and the infrastructure (i.e. the basic physical and organizational structures and facilities, such as buildings, roads, power supplies) needed for the operation of a society or enterprise. They are typically physically consumed in the process of being experienced, such as when plants or animals are transformed into food, energy, or materials for shelter or ornamental purposes.

Nature's non-material contributions to people refers to nature's contribution to people's subjective or psychological quality of life, individually and collectively. The entities that provide these intangible contributions can be physically consumed in the process (e.g., animals in recreational or ritual fishing or hunting) or not (e.g., individual trees or ecosystems as sources of inspiration).

Drivers of change refers to all those external factors that affect nature, anthropogenic assets, nature's contributions to people and good quality of life. They include institutions and governance systems and other indirect drivers, and direct drivers (both natural and anthropogenic).

Institutions and governance systems and other indirect drivers are the ways in which societies organize themselves and the resulting influences on other components. They are the underlying causes of environmental change that are exogenous to the ecosystem in question. Because of their central role, influencing all aspects of human relationships with nature, they are key levers for decision-making. “Institutions” encompasses all formal and informal interactions among stakeholders and the social structures that determine how decisions are taken and implemented, how power is exercised, and how responsibilities are distributed. To varying degrees, institutions determine the access to and control, allocation and distribution of the components of nature and of anthropogenic assets and their contributions to people. Examples of institutions are systems of property and access rights to land (e.g., public, common-pool or private), legislative arrangements, treaties, informal social norms and rules, including those emerging from indigenous and local knowledge systems, and international regimes such as agreements against stratospheric ozone depletion or for the protection of endangered species of wild fauna and flora. Economic policies, including macroeconomic, fiscal, monetary or agricultural policies, play a significant role in influencing people's decisions and behaviour and the way in which they relate to nature in the pursuit of benefits. However, many of the drivers of human behaviour and preferences, which reflect different perspectives on a good quality of life, work largely outside the market system.

Direct drivers, both natural and anthropogenic, affect nature directly. “Natural drivers” are those that are not the result of human activities and are beyond human control. These include earthquakes, volcanic eruptions and tsunamis, extreme weather or ocean-related events such as prolonged drought or cold periods, tropical cyclones and floods, the El Niño/La Niña Southern Oscillation and extreme tidal events. The direct anthropogenic drivers are those that are the result of human decisions, namely, of institutions and governance systems and other indirect drivers. Anthropogenic drivers include habitat conversion, e.g., degradation of land and aquatic habitats, deforestation and afforestation, exploitation of wild populations, climate change, pollution of soil, water and air and species introductions. Some of these drivers, such as pollution, can have negative impacts on nature; others, as in the case of habitat restoration, or the introduction of a natural enemy to combat invasive species, can have positive effects.

Good quality of life is the achievement of a fulfilled human life, a notion which varies strongly across different societies and groups within societies. It is a context-dependent state of individuals and human groups, comprising access to food, water, energy and livelihood security, and also health, good social relationships and equity, security, cultural identity, and freedom of choice and action. From virtually all standpoints, a good quality of life is multidimensional, having material as well as immaterial and spiritual components. What a good quality of life entails, however, is highly dependent on place, time and culture, with different societies espousing different views of their relationships with nature and placing different levels of importance on collective versus individual rights, the material versus the spiritual domain, intrinsic versus instrumental values, and the present time versus the past or the future. The concept of human well-being used in many western societies and its variants, together with those of living in harmony with nature and living well in balance and harmony with Mother Earth, are examples of different perspectives on a good quality of life.

APPENDIX 2
Communication of the degree of confidence

Figure SPM A 2 **The four-box model for the qualitative communication of confidence.**

Confidence increases towards the top-right corner as suggested by the increasing strength of shading. Source: IPBES (2016).[16]

In this assessment, the degree of confidence in each main finding is based on the quantity and quality of evidence and the level of agreement regarding that evidence **(Figure SPM.A2)**. The evidence includes data, theory, models and expert judgement. Further details of the approach are documented in the note by the secretariat on the information on work related to the guide on the production of assessments (IPBES/6/INF/17).

- **Well established:** there is a comprehensive meta-analysis or other synthesis or multiple independent studies that agree.
- **Established but incomplete:** there is general agreement, although only a limited number of studies exist; there is no comprehensive synthesis, and/or the studies that exist address the question imprecisely.
- **Unresolved:** multiple independent studies exist but their conclusions do not agree.
- **Inconclusive:** there is limited evidence and a recognition of major knowledge gaps.

Freitas, N. Gallai, P. G. Kevan, A. Kovács-Hostyánszki, P. K. Kwapong, J. Li, X. Li, D. J. Martins, G. Nates-Parra, J. S. Pettis, R. Rader, and B. F. Viana (eds.)., secretariat of the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services, Bonn, Germany, 2016. Available at http://doi.org/10.5281/zenodo.2616458.

APPENDIX 3
Knowledge gaps

In the course of conducting this assessment key information needs were identified. See draft table Appendix IV.

- Data, inventories and monitoring on nature and the drivers of change
- Gaps on biomes and units of analysis
- Taxonomic gaps
- NCP-related gaps
- Links between nature, nature's contributions to people and drivers with respect to targets and goals
- Integrated scenarios and modelling studies
- Potential policy approaches
- Indigenous peoples and local communities

APPENDIX 4
Draft table of knowledge gaps

Disclaimer: This table of knowledge gaps was prepared by the experts of the Global Assessment and presented to and considered by a working group established by the Plenary at its seventh session. The Plenary did not approve this table as part of the summary for policymakers. It is therefore included in draft form, which does not imply working group or Plenary approval.

Sector	Knowledge gaps (in data, indicators, inventories, scenarios)[17]
Data, inventories and monitoring on nature and the drivers of change	• Data on ecosystem processes (including rates of change) that underpin nature's contributions to people and ecosystem health • Data from monitoring of ecosystem condition (generally less well represented than ecosystem extent) • Data on changing interactions among organisms and taxa • Impacts of increasing CO_2 upon the total Net Primary Production of marine systems, and consequences for ecosystem function and nature's contributions to people • Syntheses of how human impacts affect organismal traits and global patterns and trends in genetic composition • Data on extinction risks and population trends, especially for insects, parasites and fungal and microbial species • Indicators on the global extent and consequences of biotic homogenization, including genetic homogenization • Global spatial datasets on key threats, e.g., data on patterns in the intensity of unsustainable exploitation of species and ecosystems • More comprehensive understanding of how human-caused changes to any Essential Biodiversity Variable class (e.g., ecosystem structure) have impacts on others (e.g., community composition) and on nature's contributions to people • Data gaps in key inventories: World Database on Protected Areas, the World Database of Key Biodiversity Areas™, red lists of threatened species and ecosystems, and the Global Biodiversity Information Facility • Monitoring of many listed species in the Convention on International Trade in Endangered Species of Wild Fauna and Flora. • Monitoring of the long-term effects of dumped waste, especially radioactive material and plastics • Data on the impacts of war and conflict on nature and nature's contributions to people
Gaps on biomes and units of analysis	• Inventories on under-studied ecosystems: freshwater, Arctic, marine/ocean, seabed, and wetlands • Inventories in soil, benthic and freshwater environments, and the implications for ecosystem functions
Taxonomic gaps	• Basic data on many taxa (86 per cent of existing species on Earth and 91 per cent of species in the ocean still await description) • Extinction risks and population trends for the following taxonomic groups: insects, fungal species, microbial species (microorganisms) and parasites • Data on the genetic diversity and conservation status of breeds of farmed and domestic plants and animals
NCP-related gaps	• Data on the status of species and nature's contributions to people linked to specific ecosystem functions • Systematic indicators to report the status and trends for categories of nature's contributions to people • Data on the impacts and extent of nature's contributions to people on quality of life, by major user group (also lacking an agreed typology on major user groups) • Data on the interrelationships between gender equality, nature and nature's contributions to people • Data and information on NCP 10: regulation of detrimental organisms and biological processes (populations of vectors and vector-borne diseases) and overlaps with vulnerable human populations and ecosystem interactions • Data and information on NCP 9: the role of nature and nature's contributions to people in mitigating or reducing vulnerability to disasters

17. This list of knowledge gaps in the IPBES Global Assessment of Biodiversity and Ecosystem Services is not exhaustive.

Sector	Knowledge gaps (in data, indicators, inventories, scenarios)[17]
Links between nature, nature's contributions to people and drivers with respect to targets and goals	• Understanding on how nature contributes to achieving targets (the positive and negative relationships between nature and targets/goals like the Sustainable Development Goals) • Disaggregated data on the impacts that nature has on good quality of life, particularly across regions, societies, governance systems, and ecosystems • Need for indicators for some Sustainable Development Goals and Aichi Biodiversity Targets (e.g., Aichi Biodiversity Target 15 on ecosystem resilience and contribution of biodiversity to carbon stocks and Target 18 on integration of traditional knowledge and effective participation of indigenous peoples and local communities) • Better quantitative data to assess the Sustainable Development Goals and Aichi Targets where qualitative indicators havebeen dominant (9 out of 44 targets under the Sustainable Development Goals reviewed) • Data on the benefits to human mental health from exposure to natural environments • Indicators that reflect the heterogeneity of indigenous peoples and local communities
Integrated scenarios and modelling studies	• Regional and global socioeconomic scenarios explicitly considering the knowledge, views and perspectives of indigenous peoples and local communities • Regional and global ssocioeconomic scenarios developed for, by and in collaboration with indigenous peoples and local communities and their associated institutions • Quantitative data showing how nature, its contributions to people, and good quality of life interact and change in time along different pathways • Scenarios of the future of biodiversity which quantify the possible co-benefits related to nature's contributions to people • Scenarios about nonmaterial benefits to people compared to material benefits and regulating benefits • Integrated scenarios for areas projected to experience significant impacts and possible regime shifts (e.g., Arctic, semi-arid regions, and small islands) • Knowledge about the interaction, feedback and spill-overs among regions within future global scenarios • Assessment of nature's contributions to people across scenario archetypes with robust knowledge and quantitative estimates
Potential policy approaches	• Data to analyse the effectiveness of many policy options and interventions, including: a) Data on the comparative effectiveness of different area-based conservation mechanisms (e.g., protected areas, other effective area-based conservation measures) in conserving nature and nature's contributions to people and contributing to good quality of life b) Indicators of the effectiveness of different restoration methodologies and to assess restoration progress over time (including values) c) Data on the comparative effectiveness of different processes of access and benefit sharing to ensure fairness and equity d) Better data on the global extent and forms of wildlife trafficking and its impacts on nature and nature's contributions to people e) Data on the comparative effectiveness of different models for reconciling bioenergy and biodiversity conservation f) Data on the effectiveness of different schemes and models for payment for ecosystem services (PES), particularly the trade-offs that arise between policy goals, the integration of multiple values in PES, data on the profiles of PES participants and long-term monitoring of relational and behavioural implications of participation g) Data on the comparative effectiveness of different models of marine governance relating to conservation • Data on the extent of the participation of indigenous peoples and local communities in environmental governance • Indicators on the impacts of environmentally harmful subsidies and trends and effectiveness of their removal at the global level • Data on areas of uncertainty in applying the precautionary principle • Data on the monitoring of policy effectiveness to adapt and adjust policies and to share lessons • Data on the impacts of resource mobilization, using robust program evaluation methods (e.g., examples of successful use of funding including impacts of donor funding for conservation and impacts of specific biodiversity financing projects) • Data on the impacts of climate change on marine and coastal governance regimes • Data on the impacts of mainstreaming of biodiversity across sectors • Better data to develop biodiversity and environmental quality standards
Indigenous Peoples and Local Communities	• Agreed-upon methods to enable systematic processes of knowledge generation, collection and synthesis regarding indigenous and local knowledge (for assessments and elsewhere) and participation of indigenous peoples and local communities in this process • Syntheses of indigenous and local knowledge about the status and trends in nature • Data to assess how progress in achieving goals and targets affects indigenous peoples and local communities, either in positive or in negative ways • Trends in relation to the socioeconomic status of indigenous peoples and local communities (e.g., noting the lack of data differentiation in aggregate statistics)

CHAPTER 1

ASSESSING A PLANET IN TRANSFORMATION: RATIONALE AND APPROACH OF THE IPBES GLOBAL ASSESSMENT ON BIODIVERSITY AND ECOSYSTEM SERVICES

1.1 SETTING THE STAGE

1.1.1 The scope of the IPBES Global Assessment on Biodiversity and Ecosystem Services

The challenges of mitigating and adapting to climate change, achieving inclusive food, water, energy and health security, addressing urban vulnerabilities, and the unequal burdens of nature deterioration, are not only predicaments on their own right. Because they interact, often exacerbating each other, they create new risks and uncertainties for people and nature. It is now evident that the rapid deterioration of nature, including that of the global environmental commons on land, ocean, atmosphere and biosphere, upon which humanity as a whole depends, are interconnected and their cascading effects compromise societal goals and aspirations from local to global levels. Growing efforts to respond to these challenges and awareness of our dependence on nature have opened new opportunities for action and collaboration towards fairer and more sustainable futures.

The global assessment on biodiversity and ecosystem services (GA) has been designed to be a comprehensive and ambitious intergovernmental integrated assessment of recent anthropogenic transformations of Earth's living systems, the roots of such transformations, and their implications to society. In the chapters that follow, our mandate is to critically assess the state of knowledge on recent past (from the 1970s), present and possible future trends in multi-scale interactions between people and nature, taking into consideration different worldviews and knowledge systems, including those representing mainstream natural and social sciences and the humanities, and indigenous and local knowledge systems. In doing so, the GA also assesses where the world stands in relation to several international agreements related to biodiversity and sustainable development.

This challenging task, mandated by the 123 member-countries (2016) of the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES), reflects the evolution of international collective thinking and action and fulfils several goals. It reflects an increasingly shared understanding that the human imprint at a global scale has made our social worlds intertwined with the larger Earth biophysical systems and fabric of life. It represents a shared understanding that internationally agreed goals for sustainable development, biodiversity conservation and climate change are interdependent in their pathways to success. As such, the GA examines our past trajectories, our actions today and the opportunities going forward as part of an interdependent global social-ecological system, with its own emergent properties, undergoing fast changes and modes of functioning. Earth history has become intertwined with human history. At the same time, it is increasingly obvious that the planet is highly heterogeneous and yet highly interconnected, physically and virtually, socially as well as ecologically. Global connectivity and unity do not mean uniformity; shared goals do not mean a single pathway.

To accomplish its goals, the GA examines the current status, past and future trends in nature, development pathways across world regions, interactions between and among direct and indirect drivers of change within and across them, human values towards the environment and response options regarding nature both on land and under water and nature's contributions to people's quality of life in landscapes and seascapes under different degrees of human intervention. A hallmark component of the GA is its systematic cross-chapter and cross-scale attention to indigenous and local knowledge (ILK) and issues concerning Indigenous Peoples and Local Communities (IPLCs), scaling-up and providing syntheses, where appropriate, at regional and global levels.

The timeframe examined in the assessment includes going back as far as 50 years (or longer) so that current status and trends up to 2020 can be seen in context. Scenarios and plausible future projections are examined with a focus on various periods between 2020 and 2050, covering key target dates related to the Strategic Plan for Biodiversity 2011–2020 and the 2030 Agenda for Sustainable Development and its Sustainable Development Goals, as well as overall trends across the next 50 years. An important aspect of the GA is to examine the synergies and trade-offs associated with meeting multiple goals and the interactions among the social, economic and environmental dimensions underlying possible pathways to the future. Another major goal is to examine policy options and solutions in an integrated way, so that specific goals such as feeding the world, sustaining the world's fisheries, mitigating climate change, or providing water security to all do not undermine, but rather leverage on each other.

This task is structured according to five overarching questions defined in the global assessment scoping report[1]:

(a) What is the status of and trends in nature, nature's contributions to people and indirect and direct drivers of change?

(b) How do nature and its contributions to people influence the implementation of the Sustainable Development Goals? What is the evidence base that can be used for assessing progress towards the achievement of the Aichi Biodiversity Targets?

(c) What are the plausible futures for nature, nature's contributions to people and their impacts on quality of life between now and 2050?

(d) What pathways and policy intervention scenarios relating to nature, nature's contributions to people and their impacts on quality of life can lead to sustainable futures?

(e) What are the opportunities and challenges, as well as options available to decision makers, at all levels relating to nature, its contributions to people and their impacts on quality of life?

The assessment of evidence regarding these five questions is guided by the IPBES conceptual framework and a series of analytical frameworks described in this chapter. The GA builds upon a series of preceding IPBES assessments, which include an assessment on pollination (IPBES, 2016a), a methodological assessment of scenarios and models (IPBES, 2016b), four regional assessments (IPBES, 2018b, 2018c, 2018d, 2018e) and the land degradation and restoration assessment (IPBES, 2018a). Besides its specific mandate, the GA addresses issues of a global nature not fully covered in those assessments, paying particular attention to inter-regional interactions and their emergent global outcomes.

1. Annex I to decision IPBES-4/1, 2016.

The goal of the GA is to provide relevant, credible, legitimate, authoritative, evidence-based, and comprehensive analyses of the state of knowledge these questions, informing a range of stakeholders in the public and private sectors and civil society. These include governments, multilateral organizations, the private sector and civil society, including IPLCs and non-governmental organizations. The assessment is organized to contribute directly – although by no means exclusively – to the evaluation of the UN Convention on Biological Diversity's (CBD) Strategic Plan for Biodiversity 2011–2020 (including the Aichi Biodiversity Targets) and its 2050 Vision for Biodiversity. It informs the upcoming fifth edition of the Global Biodiversity Outlook (GBO) of the Convention on Biological Diversity, which in 2020 will report on the implementation and the achievements of the Strategic Plan for Biodiversity 2011–2020 and consider ways forward.

The GA also contributes to the evaluation of progress towards achieving the 2030 United Nations Sustainable Development Goals (SDGs), particularly goals related to the natural environment and biodiversity. The GA also assesses progress towards ten other environment-related international agreements (see description of chapter 3 below), and intends to contribute, among others, to national and regional assessments and strategies. Evaluations of these agreements and the guiding questions presented above consider current and projected climate change scenarios and proposed pathways to achieve the goals of the Paris Agreement on Climate.

A road map to the chapters of the Global Assessment

As other IPBES assessments, the GA is a critical evaluation of the state of knowledge carried out under the principles of relevancy, legitimacy and credibility. The GA has not undertaken new primary research, but analysed, synthetized and critically evaluated available information and data previously published or otherwise made available in the public domain in a traceable way. The questions presented above provide a framework for evaluating and integrating evidence from local to global levels, spanning past and future.

The GA chapters are organized to accomplish a two-fold goal: to provide in-depth knowledge on specific issues and domains (using diverse expertise and perspectives, evidence and indicators), and to build upon each other in the spirit of cumulative understanding of cross-cutting issues. For instance, chapter 1 provides a common framework, language, and set of analytical tools that supports all chapters; the three subchapters of chapter 2 provide detailed evidence on status and trends to date, providing support for chapter 3 to examine progress towards the 2011–2020 Aichi Biodiversity Targets, the 2030 SDGs, and other environmental agreements; both chapters provide the

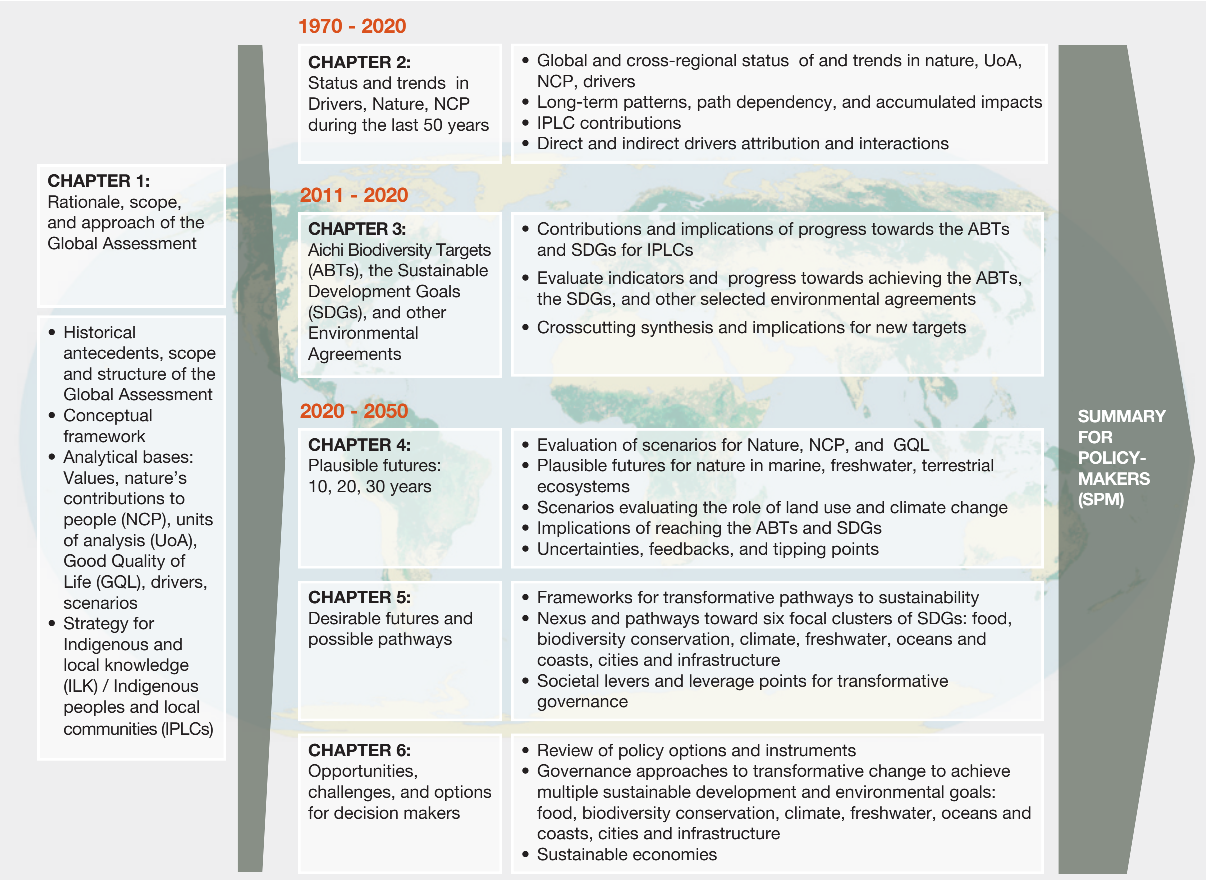

Figure 1 1 **A schematic representation of the chapters of the Global Assessment (GA).**

elements for the analyses presented in chapters 4, 5, and 6. Together, the chapters develop a storyline starting with the social-ecological transformation of the Earth particularly during the past 50 years, examining current progress in confronting the challenges posed by such transformation, evaluating the outlook of the near and more distant futures, and reflecting the potential pathways and policy options to fairer, more resilient and sustainable futures.

1.1.2 The chapters: Unfolding the story of global changes and what to do about them

What follows in chapter 1 starts with contextualizing the GA within a longer lineage of efforts to understand global changes and possible pathways to sustainability. It then provides a detailed discussion of the IPBES conceptual framework supporting the assessment, explaining its main elements and interactions. The nature's contribution to people approach is presented as a product of evolving ideas since the popularization of ecosystem services concepts and approaches. Next, this approach and its derived analytical categories are explained, followed by a presentation of other key analytical tools used in the assessment, including values towards nature, institutions and governance, good quality of life, direct and indirect drivers, and units of analysis. This is followed by a detailed discussion of the operational strategy to integrate and scale-up from local to global levels, and systematically across chapters, issues concerning IPLCs and evidences from ILK. Finally, other supporting tools used in the assessment are presented, including scenarios, indicators, literature review, units of analysis, typology of drivers and confidence framework.

Chapter 2 addresses the question *What are the current status as well as the trends for nature, nature's contributions to people, and their indirect and direct drivers?* Given its enormous scope, the chapter is broken into three subchapters.

The first of chapter 2 subchapters (2.1), *Drivers*, examines the status and trends for drivers that affect nature directly (arrow 3 of the IPBES conceptual framework, **Figure 1.2**), and indirectly (arrow 2), including across regions. It emphasizes anthropogenic drivers and examines the development trajectories for different groups of countries, during the past 30–50 years, given their economic and environmental interactions. It considers how values and their expressions in decisions affect demands for contributions from nature, given related socioeconomic processes including evolving governance institutions (arrow 1), and how these indirect drivers in turn affect direct drivers acting directly on nature and their aggregated consequences (arrow 2).

The second subchapter (2.2), *Nature*, unpacks the nature box of the IPBES conceptual framework. After setting the stage by discussing different perspectives and worldviews about nature, it outlines nature's many different aspects, such as biodiversity and ecosystem structure and function, and the contributions of IPLCs to wild and domesticated biodiversity and to their management and conservation. The subchapter assesses status and trends of nature, using both a wide array of globally relevant indicators from marine, terrestrial and freshwater ecosystems and the first global synthesis of IPLCs indicators of local-scale change. It assesses the relative impacts of the main direct drivers on nature globally (arrow 3) as well as reports on each unit of analysis. This subchapter also describes how the many facets of nature underpin its contributions to people (arrow 4).

The third of Chapter 2 subchapters (2.3), *Nature's Contributions to People (NCP)*, describes status and trends of nature's contributions, both positive and negative, to human quality of life. This section presents a summary of status and trends globally, and highlights differences across ecosystem types and regions, for 18 NCP that span regulating, material, and non-material contributions. This section discusses the co-production of NCP by people and nature, as well as the impact that NCP has on different user groups. This section also examines multiple dimensions of value that describe impacts on human quality of life.

Chapter 3 addresses the questions of *How much progress has been made towards the Aichi Biodiversity Targets and the objectives of other biodiversity-related agreements, and how do nature and its contributions to people contribute to the implementation of the Sustainable Development Goals?* Building upon findings from chapter 2 and additional evidence from analyses of indicators and literature reviews, the chapter assesses progress towards meeting major international objectives related to biodiversity and sustainable development, with special attention given to the Aichi Biodiversity Targets and to relevant (i.e., directly biodiversity-related) Sustainable Development Goals. The chapter also examines the objectives of other biodiversity-related agreements: Convention on Migratory Species (CMS), Convention on International Trade in Endangered Species (CITES), Ramsar Convention on Wetlands (Ramsar), Convention to Combat Desertification (UNCCD), World Heritage Convention (WHC), International Plant Protection Convention (IPPC), Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR), the Arctic Council's Conservation of Arctic Flora and Fauna (CAFF), the International Treaty on Plant Genetic Resources for Food and Agriculture (ITPGRFA), and the Convention on the Law of the Sea (UNCLOS). The chapter assesses the contributions of Indigenous Peoples and Local Communities (IPLCs) to achieve biodiversity goals and targets, and how progress towards them (or lack of it) affects IPLCs. Chapter 3 also discusses the reasons for variation in progress towards international objectives, and the implications for the development of a new generation of targets towards the CBD 2050 Vision for Biodiversity.

One of the innovations of the GA is to explore target-seeking scenarios related to desirable futures, possible pathways, and their trade-offs in Chapters 4 and 5. They build upon previous chapters to assess the evidence of plausible future trends (4) in nature, nature's contributions, and quality of life; and possible pathways (5) to sustainable futures.

Chapter 4 addresses the question *What are the plausible futures for nature, nature's contributions to people and their implications for a good quality of life?* It does so by considering a wide range of scenarios of direct and indirect drivers, from business-as-usual to transformative sustainability. In line with the 2030 SDGs and the CBD 2050 Vision for Biodiversity, the chapter focuses on the 2030 and 2050 timeframes, but also includes projections to the end of the 21st century. Using statistical extrapolations, exploratory scenarios of direct and indirect drivers, and inferences from patterns in case studies derived from an extensive systematic literature review, the chapter examines these trends for terrestrial, marine, and freshwater systems, including the projected impacts of climate change on them, and the relative roles of direct drivers such as climate change, atmospheric CO_2 concentration and land use in terrestrial systems. These trends are then linked to their potential impact on the Aichi Targets and the SDGs. It also addresses potential interactions and feedbacks among nature, nature's contributions, and quality of life, including possible implications for regime shift and tipping points, and adaptive capacity. The systematic review of the literature evidenced a paucity of global scale scenarios accounting for important drivers such as pollution or invasive alien species, and concerns about Indigenous Peoples and Local Communities.

Chapter 5 addresses the question *What pathways and policy intervention scenarios relating to nature, its contributions to people, and their impacts on quality of life can lead to sustainable futures?* In doing so, the chapter focuses in particular on the means of achieving internationally agreed upon goals and targets broadly related to biodiversity and ecosystem functions and their societal benefits. Building upon and expanding the literature review carried out in Chapter 4, the chapter includes a nexus analysis of pathways toward six focal clusters of SDGs, including potential synergies and trade-offs. These six foci include *feeding the world without degrading nature on land* (SDGs 15, 2, 12), *meeting climate goals while maintaining nature and its contributions to people* (SDGs 7, 2, 13, 15), *conserving and restoring nature on land while contributing positively to human well-being* (SDGs 15, 3), *maintaining freshwater for nature and humanity* (SDGs 6, 2, 12), *securing food provisioning and nature protection in oceans and coasts* (SDGs 14, 2, 12), and *resourcing growing cities while maintaining the nature that underpins them* (SDGs 11, 15). The chapter then synthesizes cross-cutting findings from the nexus analysis and integrates other broad and diverse scholarship on social transformation to derive common constituents of sustainable pathways, using the metaphor of 'levers' and 'leverage points' of societal change. These interventions and points of intervention together lay out bold but achievable pathways to deep and lasting change that would sustain and improve the state of nature and human quality of life in the coming century.

Finally, Chapter 6 addresses the question *What are the opportunities and challenges, as well as options available to decision makers, at all levels relating to nature, its contributions to people, and their impacts on quality of life?* Building upon previous chapters, and closely aligned with the nexuses and pathways discussed in Chapter 5, this chapter focuses on assessing opportunities and challenges for decision makers at all levels to engender transformative change by integrating governance approaches that are integrative (addressing policy incoherence), inclusive (advancing mechanisms that enable participation), informed (based on legitimate and credible knowledge), and adaptive (governance that enables learning). This analysis provides a framework to examine transformative governance of five overarching issues following the discussion of pathways and levers in Chapter 5. These include integrated approaches applied to sustainable management and conservation of landscapes, coastal and marine areas, freshwater systems, cities and urban areas, and energy and infrastructure. In each case, the chapter examines the advances and setbacks of existing policy instruments, their implications for different stakeholder groups, and further advances needed to address current and emerging governance challenges. Finally, the chapter pays attention to factors affecting transformations towards sustainable economies, including the role of societal values behind economic development models, distortions and disparities in trade, tackling inequalities, developing more inclusive economic accounting, and improving financing for biodiversity and the environment.

In addition to the main body of each chapter, an extensive set of Supplementary Material is available, providing further information and preserving relevant supporting evidence and documentation.

1.2 THE IPBES GLOBAL ASSESSMENT IN THE CONTEXT OF OTHER ASSESSMENTS

The GA is part of a lineage of environmental assessments, and as such it builds upon the experiences and rules of practice of previous assessments of the global environment, biodiversity and ecosystem services, oceans and climate change, including four notable assessment reports completed on a global scale with strong focus on environmental change, biodiversity and ecosystem services, namely the Global Environmental Outlook Series (GEO), the Global Biodiversity Assessment (Heywood & Watson, 1995), the Millennium Ecosystem Assessment[2] (MA 2005), and the Global Biodiversity Outlook (GBO) and the Local Biodiversity Outlook (LBO) series. Benefiting from this rich heritage, the GA is also innovative on several fronts (**Box 1.1**: The global assessment innovative approach).

Efforts to develop evaluations of the global environment date back to the 1960s, benefiting from pioneer initiatives such as the International Biological Program (IBP), which set out a collaborative and international research agenda seeking to understand the 'biological underpinnings of productivity and human welfare'. IBP also influenced the creation of UNESCO's Man and Biosphere program in 1971 and its vision to bring together natural and social sciences to collaborate on understanding human-environment relationships. The 1972 Club of Rome's "The Limits to Growth" report and *World3* simulation model had a major influence on both global sustainability thinking and analytical approaches to global level human-environmental analysis; *World3* pioneered modelling interactions between scenarios of population, economic, and industrial growth, food production and resource uses, and limits to global ecological systems. During the 1980s, numerous initiatives emerged, among others, the Worldwatch Institute State of the World report series (starting in 1984), the World Conservation Strategy report developed by UNEP, IUCN, and WWF (starting 1980), and the influential Brundtland report 'Our Common Future' (1987).

Equally important to our current understanding of global environmental and climate change, and global sustainability more broadly, were the emergence of international research networks and programs since 1980. In just over a decade, under the auspices of various international organizations, four main research programs emerged, the World Climate Research Program (WCRP), the International Geosphere Biosphere Program, DIVERSITAS, and the International Human Dimensions Program (IHDP). Later, these programs

2. https://www.millenniumassessment.org/en/About.html

collaborated on cross-cutting issues through the integrated Earth Systems Science Partnership (ESSP), eventually coming together within the current Future Earth program. Under their umbrellas, research projects/programs covering virtually all aspects of human-environment interaction developed, many of which continue to flourish today. These programs and projects continue to provide scientific knowledge and conceptual underpinnings which have been key to efforts such as, among many others, the IPCC and IPBES.

The first comprehensive large-scale international biodiversity assessment was the Global Biodiversity Assessment (Heywood & Watson, 1995), which was proposed in 1992 in an effort to, for the first time, mobilize the scientific community to evaluate the global status of biodiversity. This endeavor was initiated by the Global Environment Facility (GEF)'s Scientific and Technical Advisory Panel (STAP) and overseen by UNEP. The GBA, however, was not an intergovernmental process and did not have a mechanism for involving multiple stakeholders, including decision-makers; which limited its policy reach even though the assessment included policy implications (Watson & Gitay, 2007).

At the turn of the millennium, in response to biodiversity-related conventions (e.g., Convention on Biological Diversity [CBD], Ramsar Convention on Wetlands, the Convention on Migratory Species, [CMS], Convention to Combat Desertification [UNCCD]) and a request by the United Nations Secretary-General (2000)[3], another major, one-time global assessment centered on the relationship between ecosystem services and human well-being was initiated: the Millennium Ecosystem Assessment (MA). The MA, completed in 2005, covered the status and trends in biodiversity, ecosystems and their services, plausible future scenarios, and options for action, and a series of sub-global assessments, which continued after the publication of the MA. Although its external review included governments as well as experts, and its board included representatives of end user groups such as biodiversity-related conventions, UN agencies, business, some national governments and civil society, the MA is considered a non-governmental assessment as its key findings were formally approved by their board, not by governments. The legacy of the MA has been major in mainstreaming the relationship between ecosystem services and human wellbeing and in motivating international interdisciplinary collaborations. It also spurred an array of sub-global assessments, along with many other regional and thematic assessments carried out since 2000. Equally important, the MA motivated the emergence of The Economics of Ecosystems and Biodiversity program (TEEB), bringing together in particular economics and ecological sciences to advance the understanding of values of ecosystem services, using sectoral and cross-sectoral analyses, bringing attention to their importance to national economies (Kumar, 2010). TEEB has had both important impacts in the mainstreaming of ecosystem services in public policies and in advancing approaches and conceptualization of values in ecosystem services analyses.

Two other relevant global-level reports are the Global Biodiversity Outlook (GBO) series, CBD's flagship reports, and the Global Environmental Outlook (GEO) series, UNEP's flagship report. The GBO was initiated at the second meeting of the Conference of the Parties of the CBD (COP-2), which requested a periodic report on biological diversity providing a summary of the status of biological diversity and effectiveness of implementation measures for safeguarding biodiversity. The first edition of the GBO series was published in 2001 with their key end users being decision-makers involved in the implementation of the Convention (CBD). The GBO-5 report, to be released in 2020, will consider the IPBES global assessment as a major input. UNEP's GEO reports were initiated in 1995 at the request of member states in response to UN Agenda 21[4] and its reporting requirements, and as a response to the Brundtland report. Since its first volume in 1997, to date, five GEO reports have been published and the GEO sixth edition (GEO-6) delivered in March 2019.

In addition to the assessments mentioned above, the GA shares many features in terms of procedures, with the Intergovernmental Panel on Climate Change (IPCC) assessments. The IPCC was created 30 years ago under the joint auspices of the World Meteorological Organization (WMO) and the United Nations Environment Program (UNEP), and its first assessment report was delivered to Governments in 1990. IPBES assessments procedurally mirror those of IPCC, as IPBES rules of procedure for the preparation of deliverables (i.e., decision IPBES 3/3) are transposed from the Intergovernmental Panel on Climate Change (IPCC)[5]. While the structure of IPCC assessments differs slightly, in general these two intergovernmental assessment processes are very similar. These similarities stem from the fact that, like the IPCC, the assessment work of IPBES is mandated in response to governments' requests; it aims to inform decision-makers through policy-relevant, not policy-prescriptive statements and findings.

3. https://www.millenniumassessment.org/en/About.html

4. Agenda 21 is a comprehensive plan of action to be taken globally, nationally and locally by organizations of the United Nations System, Governments, and Major Groups in every area in which human impacts on the environment. Agenda 21, the Rio Declaration on Environment and Development, and the Statement of principles for the Sustainable Management of Forests were adopted by more than 178 Governments at the United Nations Conference on Environment and Development (UNCED) held in Rio de Janeiro, Brazil, 3 to 14 June 1992. https://sustainabledevelopment.un.org/outcomedocuments/agenda21. Accessed May 2018.

5. Procedures for the preparation, review, acceptance, adoption, approval and publication of IPCC reports – Appendix A to the Principles Governing IPCC Work (https://archive.ipcc.ch/pdf/ipcc-principles/ipcc-principles-appendix-a.pdf)

The roles of experts are similar, authors are regionally represented, and each assessment undergoes two external review rounds prior to the submission of the final government draft. In both cases, the resulting Summary for Policymakers (SPM) is negotiated in their respective plenaries among member countries. IPBES' mandate includes three functions in addition to assessments: capacity building, knowledge generation catalysis and policy support (Brooks *et al.*, 2014). Distinctively, IPBES also has an explicit mandate to embrace different knowledge systems in its assessments and functions.

The GA had seven IPBES assessments to draw from (i.e., synthesize information from) and build upon which included two thematic assessments (pollination and land degradation and restoration), one methodological assessment (scenarios and models), and four regional assessments: Americas, Africa, Europe and Central Asia, and Asia and the Pacific. Because the four regional assessments and the land degradation and restoration assessment were being undertaken almost in parallel (completed in 2018) – this meant the global assessment had the unique advantage and benefit of accessing a separate and extensive up-to-date pool of evidence (albeit somewhat overlapping) and experts that could confirm, support or contribute to the evaluations and work completed in the global assessment.

Box 1 1 **The global assessment innovative approach.**

The IPBES global assessment is the **first independent comprehensive global assessment of biodiversity, ecosystems and their contributions to people following an intergovernmental process from start to end**, as such, this assessment is **highly policy relevant** having its mandate and scope requested and approved by governments and international conventions. In addition, the geographic, gender and disciplinary **balance** of the author team has further increased this assessment's legitimacy. The global assessment is built on the innovative and inclusive **IPBES conceptual framework** explaining connections between people and nature (see Section 1.3.1 and **Box 1.2**) with institutions, governance and other indirect drivers being central to all interactions. The global assessment also made a concerted effort to include a diversity of **worldviews and knowledge systems including systematic analyses of evidence on indigenous and local knowledge and issues**, and dialogue meetings involving experts and representatives from Indigenous Peoples and Local Communities (see Section 1.3.2 and **Box 1.3** and **1.4**). The IPBES global assessment has recognized thresholds, synergies, trade-offs and feedbacks in its assessment of nature, nature's contributions to people and drivers of their changes through the concepts of **telecoupling and nexuses** – which has not been done before at the global scale; understanding these interactions (spatially and across sectors) have direct implications for considering options for action. Framed around major international agreements such as the aforementioned post-2020 biodiversity framework of the UN Convention of Biological Diversity, the Paris Agreement of the UN Framework Convention on Climate Change and the UN 2030 Agenda for Sustainable Development and its Sustainable Development Goals **– the global assessment aims to be far-reaching and to inform decision makers and end users at all scales and sectors**. The completion of this global assessment is uniquely timed to be a major input to the Convention on Biological Diversity's fifth edition of the Global Biodiversity Outlook and its second edition of the Local Biodiversity Outlook. The global assessment has assessed progress towards the current Aichi Biodiversity Targets which will inform the next set of targets and the post-2020 biodiversity framework.

1.3 THE CONCEPTUAL BASES OF THE IPBES GLOBAL ASSESSMENT

1.3.1 The IPBES Conceptual Framework

As previous IPBES assessment reports, this global assessment is structured according to the IPBES conceptual framework (CF), described in detail in Díaz *et al.* (2015a, 2015b). The CF is a highly simplified model of those interactions between people and the rest of the fabric of life on Earth that are most relevant to IPBES's goal. It intends to bring together the perspectives and information of a wide spectrum of knowledge systems and stakeholders on the status and trends of the living world and its contributions to people's quality of life. Since its inception by approval of the IPBES member countries in 2013, the CF has provided a conceptual and analytical tool that underpins all IPBES functions and provides a consistent structure and terminology to IPBES products at different spatial scales, on different themes, and in different regions. To date, it has been used successfully to guide the IPBES pollination assessment (IPBES, 2016a), the methodological assessments on scenarios and models (IPBES, 2016b), four regional assessments (IPBES, 2018b, 2018c, 2018d, 2018e), the land degradation and restoration assessment (IPBES, 2018a), and the present global assessment.

The CF includes six primary interlinked elements (or components) that operate at various scales in time and space: nature; nature's contributions to people (NCP); anthropogenic assets; institutions and governance systems and other indirect drivers of change; direct drivers of change; and good quality of life **(Box 1.2, Figure 1.2)**. These elements have been conceived as broad, inclusive categories that should be meaningful and relevant to all stakeholders involved. The CF thus provides a common ground and terminology to facilitate cross-disciplinary and cross-cultural understanding and inter-operability in the discussion of problems and the identification of solutions to common challenges.

The CF explicitly considers that formal and informal institutions mediate human-nature interactions, facilitating or hindering the co-production of NCP and the distribution of benefits to different social groups. Built upon a long lineage of conceptual frameworks, intended to facilitate interdisciplinary collaboration and science-policy dialogues, salient innovative aspects of the IPBES CF are its participatory construction and its explicit consideration of diverse disciplines, as well as diverse stakeholders (the scientific community, governments, international organizations, civil society at different levels, with Indigenous Peoples and Local Communities sometimes being part of each of these groups), and their different knowledge systems (natural sciences, social sciences and humanities, indigenous, local and practitioners' knowledge).

Particularly relevant features of the CF are:

- **Institutions and governance:** In a shift of focus with respect to most previous initiatives, the CF highlights the central role of institutions (in the broadest sense) as key indirect drivers of change and more generally as fundamental mediators of the perceptions and values about nature and NCP as well as the relationships between humans and all other forms of life on Earth.

- **Explicit consideration of different knowledge systems:** The different knowledge systems from which each of the major elements can be approached are graphically indicated using different fonts and colours for the boxes representing the main elements in **Figure 1.2**. The headlines in larger black bold font indicate the broad, highly inclusive categories nature, nature's contributions to people (NCP), good quality of life (GQL), indirect drivers, direct drivers and anthropogenic assets. The green and blue fonts indicate the more specific categories used by different disciplines and knowledge systems to refer to them. In green are some examples of common natural and economic sciences categories, and in blue, some from indigenous knowledge systems. It is important to stress that these are simply illustrations of the many categories that could be used, and that between the green and blue categories there is a wide gradient of perspectives rather than a sharp distinction. Therefore, the clear-cut distinction between the blue and green 'circuits' in the diagram is simply a means to highlight the importance of incorporating diverse perspectives into the CF.

- **Co-production of nature's contributions to people (also called joint production in Chapter 2-nature's contributions to people – NCP):** highlights the role of human societies as co-producers of NCP through anthropogenic assets (e.g., labour, knowledge, financial and built assets). This is a change in emphasis with respect to some conservation approaches that tended to see humans almost exclusively as external drivers negatively impacting nature. From a cultural perspective, co-production of NCP also provides shared meaning in society of the way interactions with nature contribute towards a good quality of life.

- **Plurality of values and interests:** The explicit recognition that there are no uniform needs (beyond those involved in physical survival), aspirations, perceptions, or preferences towards nature and NCP across the whole humankind, but rather a highly uneven, complex, constantly evolving mosaic of views, interests and stakes across and within societies. See Section 1.3.1.3.

The adoption of a single CF at the onset of IPBES was made in full recognition that a perfect alignment among the categories of different knowledge systems or even disciplines is unattainable. Representations of human–nature relationships may vary across cultures and knowledge systems in relation to specific worldviews and epistemologies, including between natural and social sciences and the humanities, scientific and indigenous knowledge systems, as well as among Indigenous Peoples and Local Communities. The CF is therefore mainly intended to provide a common platform for reflection and identification of options, rather than a comprehensive shared cross-cultural description of the world.

Box 1.2 describes the main elements of the CF, their interlinkages and the recognition of different knowledge systems as diagrammatically presented in **Figure 1.2**. A full glossary is presented as Supplementary Material 1.1.

Box 1 2 **The Main Elements of the IPBES Conceptual Framework.**

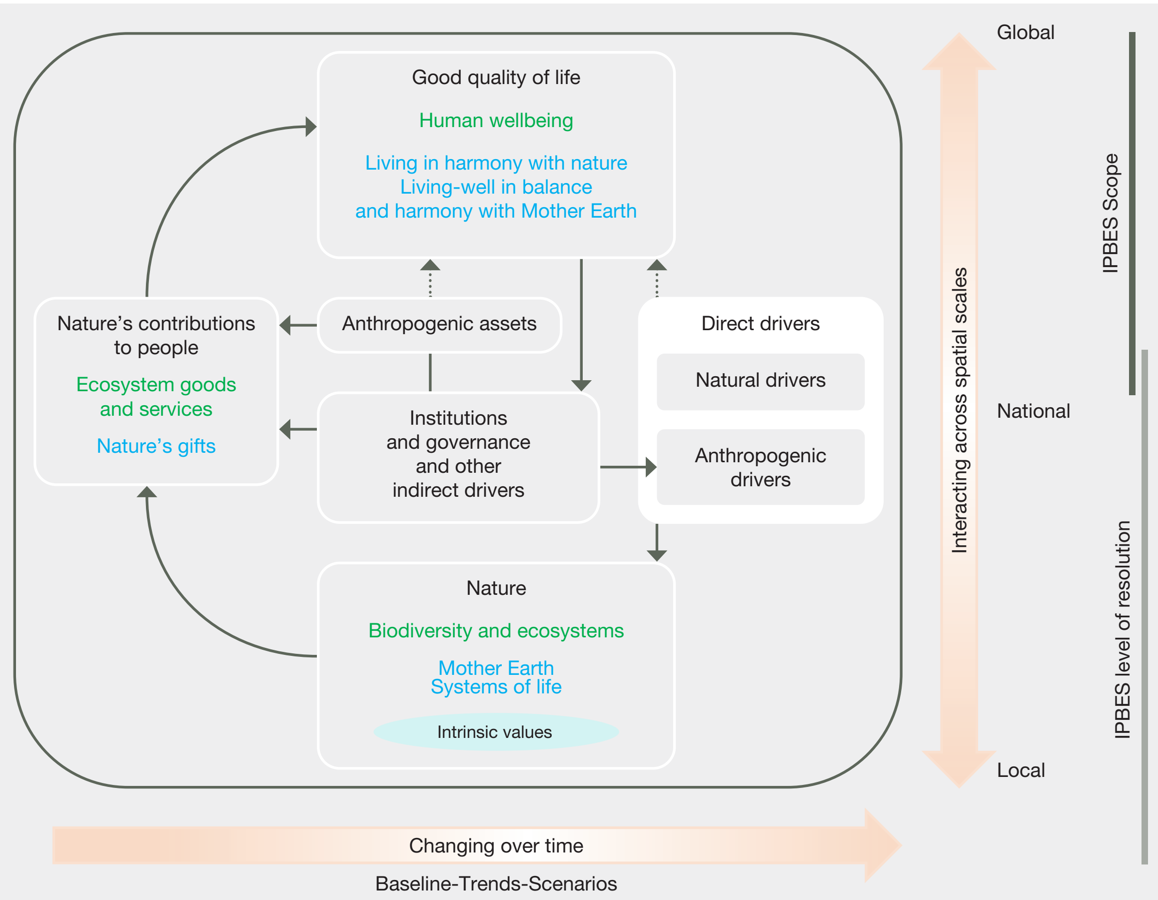

Figure 1 2 **The IPBES conceptual framework (CF). Source: Díaz *et al.* (2015a, 2015b).**

The IPBES conceptual framework is a highly simplified model of the complex interactions between the natural world and human societies. The model identifies the main elements (boxes within the main panel outlined in white), together with their interactions (arrows in the main panel), that are most relevant to the Platform's goal. "Nature", "nature's contributions to people" and "good quality of life" (indicated as black headlines and defined in each corresponding box) are inclusive categories that were identified as meaningful and relevant to all stakeholders involved in IPBES during a participatory process, including various disciplines of the natural and social sciences and the humanities, and other knowledge systems, including those of Indigenous Peoples and Local Communities. Text in green denotes scientific concepts, and text in blue denotes concepts originating in other knowledge systems. The solid arrows in the main panel denote influence between elements, and dotted arrows denote links that are acknowledged as important, but that are not the main focus of the Platform. The thick coloured arrows below and to the right of the central panel indicate the scales of time and space, respectively. The intrinsic values of nature (represented by a blue oval at the bottom of the nature box) are interpreted as being independent from human experience and thus do not participate in these arrows (see Section 1.3.1.3). See Supplementary Material 1.1 for glossary, and Díaz *et al.* (2015a) for further explanation and examples of the links indicated by the different arrows.

This conceptual framework was accepted by the Plenary in decision IPBES/2/4, and the Plenary took note of an update presented in IPBES/5/INF/24 and in decision IPBES/5/1. Further details and examples of the concepts defined in the box can be found in the glossary.

- **Nature:** (also referred as "living nature") the nonhuman world, including coproduced features, with particular emphasis on living organisms, their diversity, their interactions among themselves and with their abiotic environment. Within the framing of the natural sciences (context of science), nature include e.g., all dimensions of biodiversity, species, genotypes, populations, ecosystems, the biosphere, ecosystem functioning, communities, biomes, Earth life support's systems, and their associated ecological, evolutionary, biogeochemical processes and biocultural diversity. Within the framework of economics, it includes categories such as biotic natural resources, natural capital and natural assets. Within a wider context of social sciences and humanities and interdisciplinary environmental sciences, it is referred to with categories such as natural heritage, living environment, or the nonhuman. Within the context of other knowledge systems, it includes categories such as Mother Earth (shared by many IPLCs around the world), Pachamama (South American Andes), se¯nluo´-wa`nxia`ng and tien-ti (East Asia), Country (Australia), fonua/vanua/whenua/ples (South Pacific Islands), Iwigara (Northern Mexico), Ixofijmogen (Southern Argentina and Chile), among many others (see Díaz *et al.*, 2015a for references). Other (non-living) components of nature, such as deep aquifers, mineral and fossil reserves, and wind, solar, geothermal and wave power, are not the focus of the Platform. The degree to which humans are considered part of nature varies strongly across these categories (see Section 1.3.1.1). Many aspects of biocultural diversity (see glossary) are part of nature, while some others pertain more to what in the CF is defined as NCP and anthropogenic assets.

- **Anthropogenic assets** refer to knowledge (including indigenous and local knowledge and technical or scientific knowledge), health facilities, technology (both physical objects and procedures), work, financial assets, built-up infrastructure, among others, that, together with nature, are essential in the co-production (or joint production) of nature's contributions to people (NCP) (Díaz *et al.*, 2018; Palomo *et al.*, 2016; Reyers *et al.*, 2013). Within some cultural contexts, this co-production also involves mutual responsibility (e.g., Comberti *et al.*, 2015; Von Heland & Folke, 2014). Anthropogenic assets have been highlighted to emphasize that a good life is achieved by a co-production of benefits between nature and societies.

- **Nature's contributions to people** (NCP) are all the contributions of nature, both positive and negative, to the quality of life of humans as individuals, societies or humanity as a whole. In earlier versions of the CF, this dimension was referred to as nature's benefits to people (NBP), with exactly the same meaning; the term was changed to better reflect that it includes negative contributions (detriments) as well positive contributions (benefits). See section 1.3.1.1 for further details.

- **Drivers of change** refer to all those external factors that affect nature, and, as a consequence, also affect the supply of NCP. The CF includes drivers of change as two of its main elements: indirect drivers (all anthropogenic) and direct drivers (both natural and anthropogenic).

- **Direct drivers**, both non-human induced and anthropogenic, affect nature directly in a physical sense. Direct anthropogenic drivers are those that flow from human institutions and governance systems and other indirect drivers. They include positive and negative effects, such as habitat conversion, human-caused climate change, or species introductions. Direct non-human induced drivers can directly affect anthropogenic assets and quality of life (e.g., a volcanic eruption can destroy roads and cause human deaths), but these impacts are not the main focus of IPBES. See Supplementary Material 1.3 for a detailed typology of drivers.

- **Indirect drivers** are human actions and decisions that operate diffusely by altering and influencing direct drivers as well as other indirect drivers. They do not physically impact nature or its contributions to people. Rather, they are the root causes of the direct anthropogenic drivers that affect nature both positively and negatively. Indirect drivers include e.g., economic, demographic, institutional, technological and cultural ones. Special attention is given, among indirect drivers, to the role of institutions and governance systems, including formal and informal systems of access to land and property rights as related to any component of nature, socially shared rules, legislative arrangements, international regimes such as agreements for the protection of endangered species, and economic policies. See Supplementary Material 1.3 for a detailed typology of drivers.

- **Institutions and governance systems and other indirect drivers** are the ways in which societies organize themselves and the resulting influences on other components. They are the underlying causes of environmental change that are exogenous to the ecosystem in question. Because of their central role, influencing all aspects of human relationships with nature, they are key levers for decision-making. "Institutions" encompasses all formal and informal interactions among stakeholders and the social structures that determine how decisions are taken and implemented, how power is exercised, and how responsibilities are distributed. To varying degrees, institutions determine the access to and control, allocation and distribution of the components of nature and of anthropogenic assets and their contributions to people. Examples of institutions are systems of property and access rights to land (e.g., public, common-pool or private), legislative arrangements, treaties, informal social norms and rules, including those emerging from indigenous and local knowledge systems, and international regimes such as agreements against stratospheric ozone depletion or for the protection of endangered species of wild fauna and flora. Economic policies, including macroeconomic, fiscal, monetary or agricultural policies, play a significant role in influencing people's decisions and behaviour and the way in which they relate to nature in the pursuit of benefits. However, many of the drivers of human behaviour and preferences, which reflect different perspectives on a good quality of life, work largely outside the market system.

- **Good quality of life (GQL)** is the achievement of a fulfilled human life. It is a highly value-laden and context-dependent concept comprising multiple factors such as access to food, water, health, education, security, and cultural identity, material prosperity, spiritual satisfaction, and freedom of choice. A society's achievement of good quality of life (GQL) and the vision of what this entails strongly influences institutions and governance systems and other indirect drivers and, through them, all other elements in the CF. The vision of what a good quality of life entails also indirectly shapes, via institutions, the ways in which individuals and groups relate to nature. Likewise, institutions and governance systems reflect and can influence a society's value system and perception of what constitutes good quality of life. IPBES does not directly address this aspect of the CF in its assessments so far, but actions that governments and societies may choose to take based on the findings of the IPBES assessments often require addressing this pathway wisely. Visions, concepts and indicators of a good quality of life are highly diverse, both in cultural roots and in geographical application. Approaches applied internationally can be based on economic (e.g., gross domestic product per capita), combined economic and social (e.g., human development index, inclusive wealth) or holistic framings (living in harmony, gross national happiness index). Other approaches, more culturally specific and place-based, include e.g., Sumak Kawsay/ Buen vivir (Central Andes), teko porã (Paraguay), vida plena (Amazonian basin), shizen kyosei shakai (Japan). See Díaz *et al.* (2015a) for references.

1.3.1.1 The Nature's Contribution to People (NCP) concept and analytical framework

Nature's contributions to people (NCP), one of the six major inclusive elements of the IPBES conceptual framework (Díaz *et al.*, 2015a, 2015b; IPBES, 2014, 2017), are all the contributions, both positive and negative, of living nature (i.e., all organisms, ecosystems, and their associated ecological and evolutionary processes) to people's quality of life (Díaz *et al.*, 2018). Beneficial contributions include, e. g., food provision, water purification, and artistic inspiration, whereas aspects of nature that can be negative to people (detriments) include e.g., disease transmission and predation that damage people or their assets. Overall, the values of nature's contributions are overwhelmingly positive as they sustain people's quality of life. However, the CF explicitly recognizes potentially detrimental NCP, and the fact that generally NCP are not inherently positive or negative, but rather this depends on spatial, temporal, social or cultural context (Ango *et al.*, 2014; Rasmussen *et al.*, 2017; Saunders & Luck, 2016; Shapiro & Báldi, 2014). What constitutes a benefit or a detriment can change with time, even for the same person, given e.g., a change in socio-economic circumstances that may alter the importance assigned to a given NCP, often a given biological entity can be at the same time a source of positive and negative contributions (Rasmussen *et al.*, 2017). This is important for conceptual and practical reasons. For example, while we are still striving to document and highlight the positive contributions (benefits) we derive from nature, many of the detriments (e.g., vector-borne diseases, livestock attacks by predators, agricultural pests) have long been recognized, valued in terms of their impacts on people, and incorporated into policy decisions. Furthermore, what are generally considered positive contributions sometimes reflect the view of dominant social actors and ignore the fact that the same contribution may be perceived as being negative in the view of less powerful sectors of society (Cáceres *et al.*, 2015). This highlights the relevance of identifying trade-offs that occur among and within many NCP as well as social trade-offs. Conflict tends to arise when negative NCP experimented by some social actors are mediated or exacerbated by decisions taken by other actors.

NCP recognizes a wide range of descriptions of the human dependence on living nature. One of such descriptions is through the concept of ecosystem goods and services (considered either separately or in bundles), pioneered in the science-policy interface by the Millennium Ecosystem Assessment (2003, 2005). The concept of NCP embraces the thriving field of ecosystem service science – in itself heterogeneous in terms of existing internal framings (Chaudhary *et al.*, 2015; Droste *et al.,* 2018) – together with a diversity of other descriptions that, although perhaps not as visible in the fields of mainstream environmental sciences, are foundational in other fields of knowledge and schools of thought, especially in the social sciences and humanities, and underpin values, decisions and practices throughout the world (Turnhout *et al.*, 2013). The range of descriptions of the human dependence of living nature contemplated in the NCP approach is thus vast. On one extreme, nature is seen as a stock of natural capital (or natural assets) from which goods and services flow to humans unidirectionally (e.g., timber provided by forests) in the form of an ecological production function (reviewed in Polasky & Segerson, 2009). The flow depends on human agency and also on the existing physical and biological conditions needed for the persistence of the biological entity from which the flow originates. Improving or sustaining the condition of the biological entity would be akin to investing in natural capital from which an interest would accrue to society, i.e., the flow of goods and services. Maintaining the productive potential of the stock of natural capital to sustain the flow of services to society would be seen as an intergenerational social objective. On the other extreme are descriptions where both people and other biophysical entities are seen as having agency and being inextricably linked by reciprocal ties of mutual care and obligations (e.g., Berkes, 2012; Descola, 2013; Head, 2008; Ingold & Pálsson, 2013; Whatmore, 2006), described with e.g., the term nature's gifts used by many indigenous and non-indigenous cultures (Hill *et al.*, 2016), or services-to-ecosystems in some hybrid framings (Comberti *et al.*, 2015). The notion of nature's contributions to people is intended to embrace and include, rather than replace and exclude the abovementioned descriptions and any others in between.

A gradient of perspectives on human dependency on nature – implications for reporting

Within the context of an assessment report, a reporting system is the method of collecting, storing and synthesizing information and knowledge, and communicating findings. It should allow the re-organization and simplification of heterogeneous content from diverse sources in a way which is consistent, repeatable and easily communicable to a wide range of audiences. Specifically, the IPBES reporting system (Díaz *et al.*, 2018; Decision IPBES-5/1) contemplates a gradient of complementary approaches through which to give meaning to NCP, ranging from a generalizing to a context-specific perspective. While presented here as extremes of such a gradient for description purposes (see previous paragraph), these two perspectives do not have clear-cut limits; they are often blended and interwoven in the process of problem framing and knowledge generation and, although sometimes a particular study, field situation, research question or assessment undertaking is squarely placed within either a generalizing or a context-specific perspective, situations with a mixture of both are not uncommon (Berger-González *et al.*, 2016; Brondizio, 2017; Chilisa, 2017; Tengö *et al.*, 2017) **(Figure 1.3a)**.

Generalizing perspective: Typical of the scientific literature that has formed the basis of most large-scale environmental assessments, this perspective (represented in green at the bottom of **Figure 1.3a**) is fundamentally analytical in purpose; it seeks a universally applicable set of categories of flows from nature to people. Distinction between them intends to be sharp, following the traditions of culture-nature dichotomy, and agency tends to be attributed to people only. NCP categories can be seen at finer or coarser resolution, but can still be organized into a unified, self-consistent system. IPBES identifies 18 such categories for reporting NCP within the generalizing perspective, organized in three partially overlapping groups, defined according to the type of contribution they make to people's quality of life: regulating, material and non-material NCP.

- *Nature's material contributions to people* refers to substances, objects or other material elements from nature that sustain people's physical existence and the infrastructure (i.e., the basic physical and organizational structures and facilities, such as buildings, roads, power supplies) needed for the operation of a society or enterprise. They are typically physically consumed in the process of being experienced, such as when plants or animals are transformed into food, energy, or materials for clothing, shelter or ornamental purposes.

- *Non-material* contributions are nature's effects on subjective or psychological aspects underpinning people's quality of life, both individually and collectively. The entities that provide these intangible contributions can be physically consumed in the process (e.g., animals in recreational or ritual fishing or hunting) or not (e.g., individual trees or ecosystems as sources of inspiration). Examples include forests and coral reefs providing opportunities for recreation and inspiration, or particular organism (animals, plants, fungi) or habitat (mountains, lakes) being the basis of spiritual or social-cohesion experiences.

- *Nature's regulating contributions to people* refers to functional and structural aspects of organisms and ecosystems that modify the environmental conditions experienced by people, and/or sustain and/or regulate the generation of material and non-material contributions. For example, these contributions include water purification, climate regulation and the regulation of soil erosion.

Building on the insights of the social sciences and the humanities, the NCP approach acknowledges that culture is the lens through which all the elements of nature are perceived and valued. In other words, culture permeates through and across all three broad NCP groups, rather than being confined to an isolated category, i.e., there is no "cultural" or "non-cultural" NCP. In addition, the three broad groups explicitly overlap, implying that many of the 18 NCP categories do not squarely fit into any one of the broader NCP groups **(Figure 1.3b)**, although they may be distinguished for practical reporting reasons. Material and non-material NCP are often interlinked in most, if not all, social-cultural contexts (Chan *et al.*, 2012b). For example, food can be primarily considered as a material NCP because calories and nutrients are essential for physical sustenance, but food is also full of symbolic meaning well beyond physical survival, having other less tangible impacts on people's quality of life. The cultural lens largely determines to what degree food is a non-material contribution as well as a material one and how both types of NCP are valued.

The 18 NCP defined by IPBES under the generalizing perspective (**Figure 1.3a**, see Supplement 1.2 for more details and examples) are in some cases sharply defined contributions, and in some others represent bundles of similar contributions. They were identified through a participatory process based on several pre-existing classifications at the global and regional scales (Haines-Young & Potschin, 2013; Kumar, 2010; Millenium Ecosystem Assessment, 2005; UK National Ecosystem Assessment, 2011), as well as recent empirical and conceptual advances in ecological, social and anthropological sciences.

Context-specific perspective: Represented in blue at the top of **Figure 1.3a**, this perspective is typical, but not exclusive, of indigenous and local knowledge systems; here knowledge production does not explicitly seek to extend or validate itself beyond specific spatial contexts (Smith, 1999; Tengö *et al.*, 2017). Put differently, this perspective does not always contribute to, and may be difficult to align with more generalizing goals of attaining a universally applicable schema. While internally consistent, the categories are context-specific and usually not intended to be universally applicable. However, no acceptable standard classification or schema (equivalent to **Figure 1.3b**) is currently available, and designing or imposing one may be inappropriate (e.g., Smith, 1999). The context-specific perspective may instead present NCP as bundles that follow from distinct social-cultural practices, language and lexicon, and ethnoecological knowledge associated with forms of interaction with the environment, such as fishing, farming or hunting, including the spiritual significance encoded in places, organisms or entities such as sacred or otherwise protected trees, animals or landscapes (Berkes, 2012; Descola, 2013; Hill *et al.*, 2016). This may involve different degrees of human and non-human relationships expressed in terms of kinship and reciprocal care and obligations (Berkes, 2012; Comberti *et al.*, 2015; Hill *et al.*, 2016; Salmón, 2000; Surrallés & García Hierro, 2005; Von Heland & Folke, 2014).

The evidence produced through a particular framing, such as ecosystem goods and services, environmental services, ecological production functions stemming from natural capital, nature's gifts, or practices of care, can be aligned under the NCP framing, either within the 18 categories of the generalized perspective (which connects easily with classic ecosystem services categories, as done in e.g., the IPBES regional assessments), or by the use of context-specific descriptions (e.g., Supplementary Material 2 in Díaz *et al.*, 2018), or a combination of both (e.g., Hill *et al.*, 2016). In doing so, the NCP approach does not ignore or invalidate any pre-existing approach or metric used by different communities of practice. For example, it welcomes ecosystem services and their economic dimensions; but at the same time acknowledges that there are other ways of framing and engaging with the benefits or detriments from nature that results from different cognitive models about the links between people and the rest of the living world (Muradian & Pascual, 2018). Despite often deeply different descriptions, relations and causalities, the conclusions from such different knowledge systems and perspectives can often coincide or complement each other when it comes to searching for solutions.

The NCP reporting system thus allows the harnessing of pre-existing information, information that is being produced at the moment, or will be produced in the future, within the specific framings of different communities of practice, including those associated with ecosystem services, ethnoecology, environmental conservation, political ecology, etc. into a pluralistic and inclusive common ground. This gives the NCP reporting system maximum flexibility, because it avoids leaving the vast diversity of human-nature perspectives and descriptions out of the picture or shoe-honing them into pre-established categories and classifications that may deprive them of meaning to different stakeholders. By doing so it also accommodates different epistemic communities to collaborate in enlarging the existing knowledge base for sustainability (Pascual & Howe, 2018), to enrich each other in more level-field interactions (Tengö *et al.*, 2017), and to be leveraged in assessing the state of, and future options for nature and its benefits and risks to societies.

1.3.1.2 Evolution of thinking, approaches and terminologies on the links between nature and its contributions to people's quality of life

Like most of integrative frameworks, the CF builds on pre-existing structures and originates in the context of particular intellectual, social and political circumstances. The CF explicitly recognizes rooting in the Millennium Ecosystem Assessment (2003, 2005), its most immediate antecedent in terms of broad conceptual scope and intent. Early in the process of building IPBES, it became clear that Millennium Ecosystem Assessment framing, although useful and the

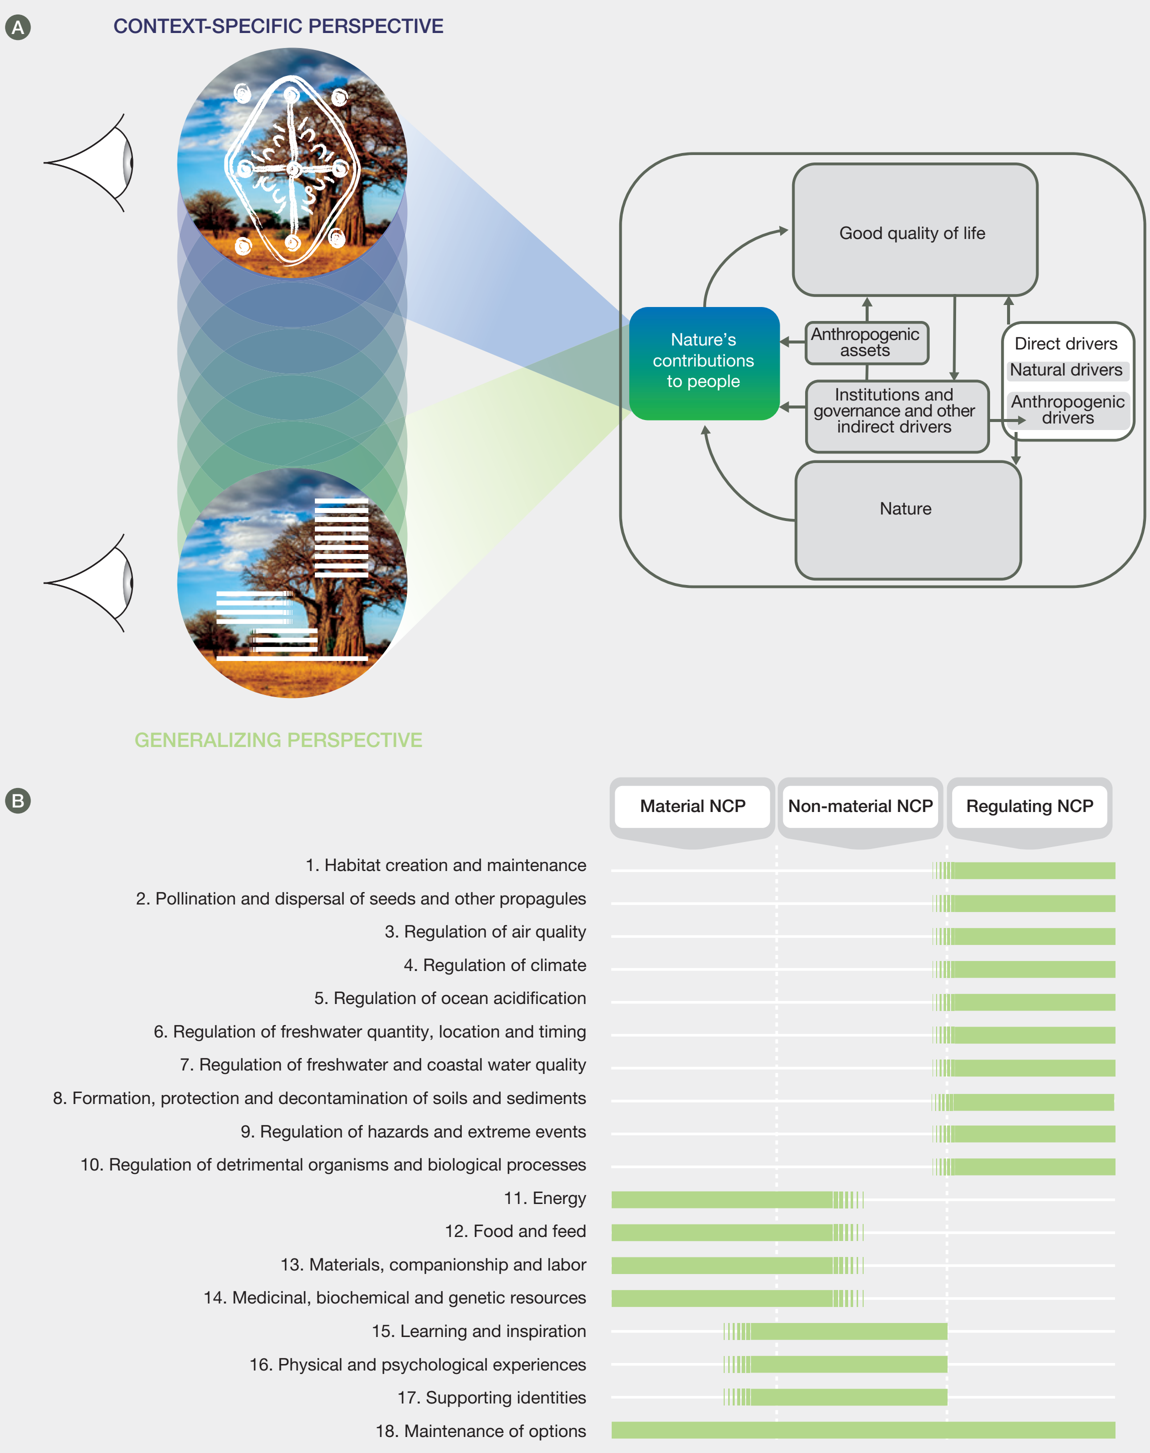

Figure 1 3 **The nature's contribution to people (NCP) approach and reporting system.**

A Two perspectives on nature's contributions to people (NCP) [Source: Díaz et al. (2018)]. NCP can be seen from the generalizing (green, bottom) or from the context-specific perspectives (blue, top). From a more generalizing perspective, 18 NCP are distinguished and organized in three broad groups – material, non-material and regulating– of general applicability (represented by the white-line figure overlapping the landscape at the bottom, shown in full in B. From a context-specific perspective these more universally applicable categories may or may not be meaningful depending on the issue and/or context. For example, a symbolic domain, such as the Warlpiri perspective on nature-human relationships (represented in a highly simplified version by white-line figure overlapping the landscape at the bottom) is only one of very many possible context-specific framings of NCP. The Warlpiri explanation of a given ecological process, however, may have significant overlap with other explanations, including a scientific one. Therefore, it is important to consider these two extremes, generalizing and context-specific perspectives, as part of a gradual transition with many potential points of overlap. Depending on the context, a stakeholder can report a specific NCP as part of any of the 18 NCP in the generalizing perspective, as part of a bundle of context-specific NCP or as transitional between the two. B The 18 NCP reporting categories used in IPBES assessments mapped onto three broad groups distinguished within the generalizing perspective [Source: Díaz *et al.* (2018)]. See main text of Section 1.3.1.1 for description of the broad groups, and chapter 2-NCP, Supplementary Material 1.2 and Díaz *et al.* (2018) for further description, examples and references concerning the 18 categories. Most NCP straddle across groups to some degree. To indicate this, the NCP in the material and non-material groups extend into their respective columns. The non-material dimension of regulating NCP is not necessarily as widely recognized across cultures; therefore, they are represented as encroaching only slightly beyond their column in the Figure. Maintenance of options (NCP 18), conveys the various dimensions of the potential opportunities offered by nature, and thus spans all three NCP groups.

most comprehensive available, would not be sufficient for the task at hand. The adoption by IPBES of a pluralistic and inclusive framework with its associated language including concepts such as nature, nature's contributions to people and quality of life was necessary on three grounds: fuller and more symmetric consideration of diverse stakeholders and worldviews, a richer evidence base to inform action, a broader inclusion of contemporary categories and questions of the social sciences and humanities. We elaborate on these three aspects below.

First, there are increasing calls for considering issues of *legitimacy, fairness, social equity* (Görg *et al.*, 2016; Pascual *et al.*, 2014) and rights (including human rights to the environment and to cultural identity; Knox, 2017) in environmental science-policy interfaces (CBD, 2010; ISSC *et al.*, 2016), and this is reflected in the mandate of IPBES. This new emphasis is partly due to a recognition that environmental decision-making has in the past often benefited majority populations (e.g., urban, wealthy, ethnic majority) with limited or negative outcomes for minority populations (e.g., rural, poor, minority groups). This can in turn have negative implications for environmental management itself, as poor, rural, indigenous or local populations are generally key actors in environmental management or deterioration. The implications of context such as gender have also been demonstrated to be of critical importance in environmental outcomes (Keane *et al.*, 2016). From the beginning, it became clear that the CF had to represent diverse views. For example, participants in the process rejected the notion that "ecosystem services", at least in its most widespread versions, effectively represented all ways of understanding the diverse contributions that nature makes to human quality of life. It was necessary to use a different term, with less baggage in any particular intellectual tradition (Castree, 2013; Rey, 1983), and with immediate meaning to as many people as possible. That different and broader term became "nature's contributions to people", with the assumption that it encompassed all the diverse and interesting research on ecosystem services, as well as other views and sources of evidence (Díaz *et al.*, 2015a, 2015b, 2018). By creating this intellectual space, IPBES does not compromise intellectual rigor; rather it recognizes the legitimacy and relevance of other views in understanding what nature can do for and with us. Therefore, through its explicit recognition of different worldviews and epistemic categories, the CF framing, including NCP, facilitates the practical incorporation of these considerations in the assessment process, and fosters broader ownership and adoption of its results across disciplinary, regional and cultural contexts. Regarding the use of terminology, the CF provides a more neutral way to refer to our links with the non-human living world in which we are inextricably linked as part of the fabric of life on Earth. We use 'people' to denote that we inclusively refer to all genders, ages, social groups (be them based on citizenship, ethnicity, class or occupation). In the broader community (i.e., beyond IPBES), different stakeholders will refer to e.g., women, children, clients, patients, particular ethnic groups, workers, entrepreneurs, etc.

Similarly, we use 'nature' to denote all non-human living entities and their interaction with other living or non-living physical entities and processes. Nature embodies different concepts for different people, including biodiversity, ecosystems, Mother Earth, Country, se¯nluo´-wa`nxia`ng and other analogous concepts (see **Box 1.2**). We use 'quality of life' to denote the vision and the achievement of a fulfilled human life. Different stakeholders will refer specifically to e.g., income, satisfaction, human development, happiness, sense of identity, vida plena, buen vivir (see **Box 1.2**). Finally, we use 'NCP' to denote all the beneficial and detrimental contributions that we obtain from and with nature. Different stakeholders, according to their goals, needs, motivations and preferences, will use other terminology such as goods, ecosystem services, gifts from nature, living natural resources, products, experiences, environmental endowments, among many others (see **Box 1.2** and Section 1.3.1.1).

Second, the IPBES CF, including the NCP concept, *expands the conceptual, methodological and empirical evidence base* from which assessments can produce options for action, and provides important opportunities for the evolution of research. The construction of the new

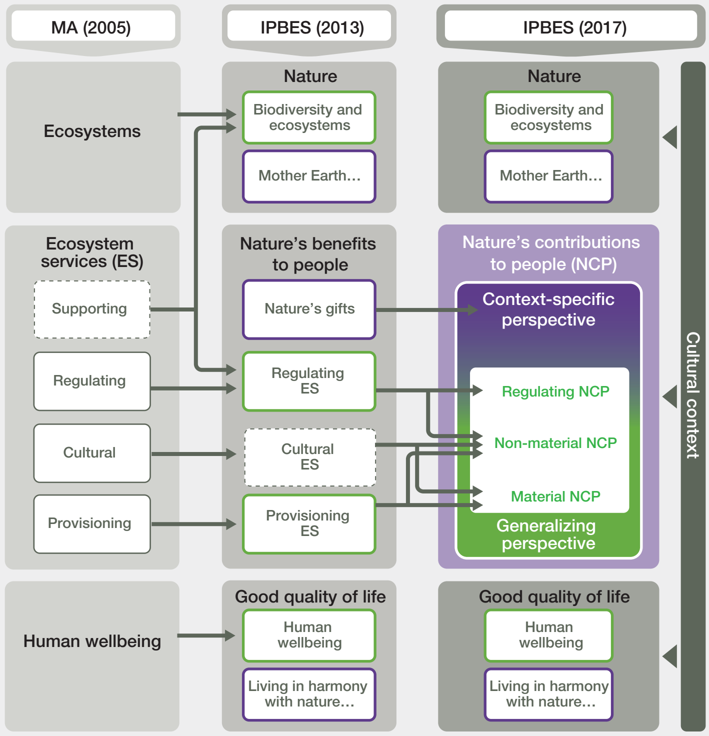

Figure 1 4 **Evolution of nature's contributions to people (NCP) and other major categories in the IPBES CF (Díaz *et al.*, 2018) with respect to the concepts of ecosystem services and human wellbeing as defined in the Millennium Ecosystem Assessment (2003, 2005).**

The element "nature's benefit to people" was adopted by IPBES Second Plenary, and further developed into NCP by the fifth session of the Platform's Plenary (IPBES-5) (Decision IPBES-5/1) in order to fully capture the fact that the concept includes all contributions to people, both positive (benefits) and negative (detriments). Concepts pointed by arrow heads replace or include concepts near arrow tails. Concepts in dotted-line boxes are no longer used: following the present view of the MA community (Carpenter *et al.*, 2009; Reid & Mooney, 2016), supporting ecosystem services are now components of nature or (to a lesser extent) regulating NCP. Cultural ecosystem services was defined as a separate ecosystem service category in the MA; IPBES instead recognizes that culture mediates the relationship between people and all NCP. For more details of NCP according to the generalizing and conceptual perspectives, see **Figure 1.3**.

framework **(Figure 1.2)** was informed by the increasing number of papers and assessments in the ecosystem service and conservation literature that had been striving to accommodate values and metrics beyond those of ecology and economics, and opened to the call from social and political sciences and humanities working from outside those paradigms to incorporate their concepts and questions and not just their data (Castree *et al.*, 2014; Nadasdy, 2011; Olsson *et al.*, 2015). In full recognition of all these intellectual streams that inspired it, the IPBES CF, including the NCP approach, strives to formalize and strengthen them in a cohesive structure suitable for operation in the science-policy interface. This additional input can have direct practical positive implications for science and policy: for example, ILK can serve to address issues of uncertainty in ecosystem management, through processes that have been honed at local levels from generations of feedback learning (Berkes *et al.*, 2000). Furthermore, it allows a more appropriate representation of concepts within and between categories of nature´s contributions or ecosystem services, building upon developments produced during the past decade, many of them within the evolving context of ecosystem service research. Prominently, it adopts the representation of culture as a crucial lens by which we understand nature and its effects, rather than as a category of service (Chan *et al.*, 2012b; Fish, 2011; Pröpper & Haupts, 2014). It takes into account critiques to the natural capital stock-and-flow model from conservation and evolutionary ecology, stressing the value of nature beyond flows and economic production functions (e.g., Faith, 2018; Silvertown, 2015). It also recognizes that people may perceive and value the contributions from nature in diverse ways, including different classes or bundles at group or individual levels (Klain *et al.*, 2014; Martín-López *et al.*, 2012; Milcu *et al.*, 2013). Non-material and material benefits from nature are often intimately intertwined, not separate categories for separate things (Chan *et al.*, 2012a; Klain & Chan, 2012; Turner *et al.*, 2008).

Finally, the IPBES CF, including the notion of NCP, allows *a broader inclusion of the categories and questions of the social sciences and humanities*. The insights above were largely derived from fields of social sciences and humanities that received scant inclusion within dominant ecosystem service framings (Daniel *et al.*, 2012; Stenseke & Larigauderie, 2017), even though these insights did percolate to some degree into the ecosystem services literature. This includes long-term acknowledged insights that human and societal interactions with nature are complex, articulated through emotions and practices, and, moreover, that human-environment relations are dynamic as social structures and physical conditions change over time (Castree, 2017; Macnaghten & Urry, 1998; Setten *et al.*, 2012). This is not restricted to ILK systems. Qualitative approaches in humanistic and social science point to a less linear understanding of human societies and social change, beyond what a systems perspective can account for (Harris, 2007; Setten *et al.*, 2012; Shove, 2010), thus requiring full attention to different cultural perspectives and value systems.

By building the above insights into the structure of the NCP approach, the hope is that NCP might better include diverse perspectives (Díaz *et al.*, 2018). Furthermore, it may help avoid the problematic simplification of relationships with nature (Faith, 2018; Norgaard, 2010; Turnhout *et al.*, 2014) and appeal to a more diverse set of social scholars, given relatively widespread reservations about ecosystem services (Dempsey & Robertson, 2012; Droste *et al.*, 2018; Satterfield *et al.*, 2013; Satz *et al.*, 2013).

In summary, like any transition in concepts and terminology and any meeting of frameworks, the challenges – conceptual, epistemological, methodological, even ontological– are formidable. Also like in any transition, there is contestation, coexistence and cross-fertilization with previous framings. For example, the ecosystem service framework, after it was created and became widespread by its adoption by the MA, coexisted for a long time, and still coexists, with the framework of renewable natural resources. Because of its flexibility, the CF framing does not require drastic re-framing of existing initiatives, organizations or research programs that do not feel the need to change, although many could easily transition to it and benefit from a wider "conversation". In other words, the concept of NCP, together with a flexible reporting system, helps IPBES to meet the requirements for successful knowledge mobilization for sustainability: legitimacy, salience, credibility and usability (Clark *et al.*, 2016; Fazey *et al.*, 2014).

1.3.1.3 Diverse conceptualization of the multiple values of nature and its contributions to people

Understanding values and their diversity, how they are conceptualized and formed and how they change over time and across contexts and scales, is critical to the understanding of human-nature relationships, and thus to inform decision-making and policy design. The ways in which nature and its contributions to people for a good quality of life are perceived and valued may be starkly different between regions, societies and sectors within societies (Martínez-Alier, 2002). Multiple values can be associated with multiple cultural and institutional contexts – different agents may assign very different values to the same object, contest the values of others, and justify their actions on the basis of such differences. Value conflicts may emerge due to uneven power relations because those with more power see their values enacted, while those with less power see their values ignored in practice (Arias-Arévalo *et al.*, 2018; Berbés-Blázquez *et al.*, 2016). Ignoring different types of values associated with material, non-material, and regulating contributions of nature and thus not incorporating them in economic decisions is considered among the most significant factors underlying the loss of nature and its contributions to people (Duraiappah *et al.*, 2014; Kumar, 2010).

The global assessment recognizes that the word 'value' is always defined in the context of a given worldview and cultural context and can refer to a preference someone has for a particular state of the world, the importance of something for itself or for others, or simply a measure (IPBES, 2015; Pascual *et al.*, 2017). Acknowledging the need for a pluralistic approach towards the values of nature and its contributions to people is necessary but not sufficient to better inform policy options intended to transform society's relationship to nature in order to achieve common societal objectives such as those expressed in the Sustainable Development Goals and the Aichi Biodiversity Targets. Given the unequal capacity by different actors to express and support their own values regarding nature in the context of decision-making, it is important for policy to capture the diversity of values and find ways to reconcile them.

Furthermore, valuation of nature and its contributions is based on a specific set of ethics and normative positions determining what value system is seen as culturally appropriate and thus applied. Such normative positions in valuation may be starkly different and even conflicting between regions, societies and sectors within societies. In general, the valuation of natural resources, ecosystem services and –more recently– NCP has tended to rely on a unidimensional-value approach, where a dominant view over nature prevails in decision-making. Most often, such views clash, as they tend to either derive from a utilitarian economic perspective, or a biocentric stance that imparts intrinsic values to species and nature. The global assessment acknowledges the influence of both value lenses and the conflicts that may arise when decision-making trumps one perspective over another; it also supports an inclusive valuation perspective consistent with the IPBES CF (Pascual *et al.*, 2017). This is important as the ways in which values are assessed carries wide implications for the analysis of trade-offs of benefits and detriments to different people, for nature, and for the future of both. For instance, when a resource is extracted from nature, embedded are the land and water inputs, the carbon emitted, the pollution produced, the biodiversity affected, the limitations on other users as well as the aesthetic beauty that some appreciate, the sacred value embedded in place, and the social relations directly or indirectly linked to such resource.

As depicted in **Figure 1.5**, the analytical framework used in the global assessment places types of values along a gradient of anthropocentric to non-anthropocentric values, including instrumental, relational, and intrinsic values, on nature, nature's contributions to people and a good quality of life (Pascual *et al.*, 2017). The colour gradient indicates that both instrumental and relational values (anthropocentric values) can be ascribed to nature's contribution to people, and highlights examples of sources of value based on what people may seek in the pursuit of a good quality of life through interaction with nature; it also explicitly includes perceived intrinsic worth (non-anthropocentric value).

The three major types of values considered in IPBES are:

- **Intrinsic values** refers to the value of an entity (e.g., an organism, an ecological process) independent of how it relates to humans.

- **Instrumental values** are associated with an entity that serves to achieve a human end, interest or preference. Instrumental value includes economic values, regardless whether the entity is directly or indirectly used, or not used (existence and bequest values).

- **Relational values** are associated to the meaningfulness of relationships, including the relationships among humans and nature and among humans, including across generations, via nature (Chan *et al.*, 2016). These values are attached to the entity itself in ways that make it not substitutable, hence not serving an instrumental or utilitarian perspective (O'Neill, 2017), and represent what people consider meaningful about nature (e.g., attachment, responsibility, commitment). Relational values can also be associated with relationships with nature towards achieving a good life, e.g., when choosing "the right thing to do" or in the context of a "meaningful life." (Pascual *et al.*, 2017).

While all types of values are considered to some degree in the global assessment, the chapters examine instrumental

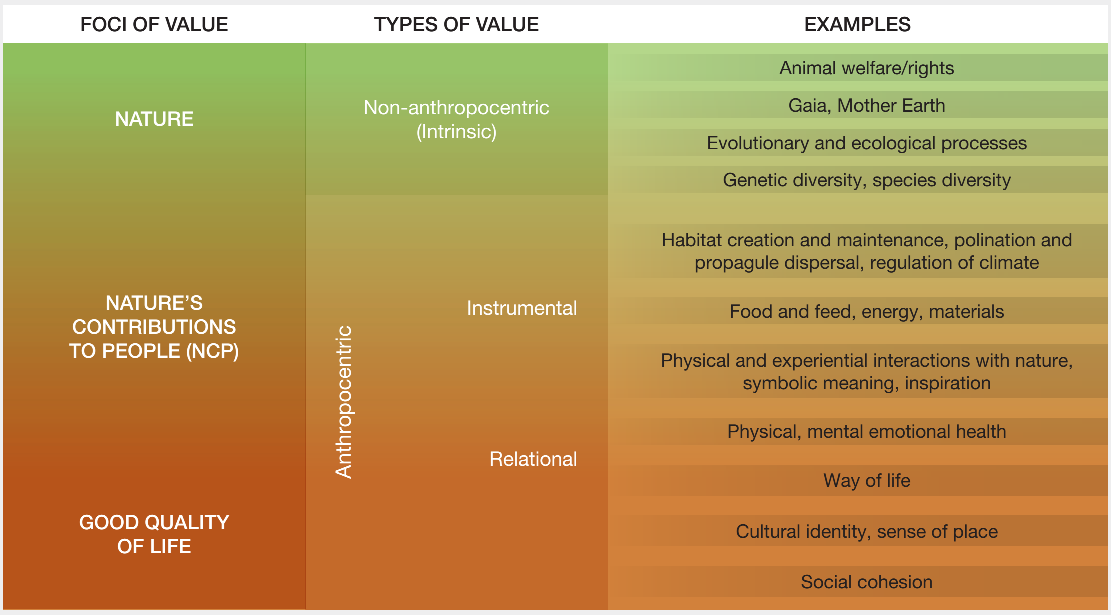

Figure 1 5 **Diverse values related to nature, nature's contributions to people (NCP) and a good quality of life (GQL), following Pascual *et al.* (2017).**

The grading in the colors indicate that both instrumental and relational values can be ascribed to the value of nature's contributions to people, and to highlight that nature's contributions to people are intertwined with nature and a good quality of life.

and relational values in much more detail. The analyses presented in Chapters 2 to 6 take into account, to various degrees, how diverse types of values underlie societies' relationships with nature, the appropriation of NCP to support a good quality of life, and the ways in which values are embedded in, and can be transformed by policy instruments and collective action.

1.3.1.4 Good quality of life – its links with nature and nature's contributions to people

Numerous conceptualizations of quality of life have been proposed over the years (Stiglitz *et al.*, 2009), combining different notions of basic human needs (Maslow, 1943; Max-Neef, 1991), freedoms and capabilities (Nussbaum, 2000; Sen, 1999), or opportunities (Costanza *et al.*, 2007). The Millennium Ecosystem Assessment (2005) represented a significant advance in recognizing multidimensional aspects of well-being and their relationships to different types of ecosystem services. The IPBES CF builds upon these efforts, recognizing that human quality of life is multidimensional, including objective and subjective dimensions, all of which pose challenges to measurement and interpretation.

Recognizing that human quality of life is a context-dependent state of individuals and human groups, the CF includes the inclusive notion of Good Quality of Life (GQL), understood as the achievement of a fulfilled human life, including material and non-material dimensions (Díaz *et al.*, 2015a). Under the umbrella of GQL, multiple concepts and terminologies may be used to reflect different sociocultural perspectives or assessment goals. For example, this includes, the concept of human well-being, which is widely used in national policy and international development reports includes subjective cultural values and personal aspirations (livelihoods, happiness, vulnerability, freedom of choice, security, etc.), relationships (social relations, action and participation in society, etc.) and access to resources (food, water, energy, shelter). It is often reported through synthetic indicators such as the 'human development index' (HDI) that build on standardized per capita income as well as other indicators such as based on education, child mortality, and life expectancy, although it does not include considerations to environmental and subjective aspects of human well-being (see **Box 1.2** for more details).

The global assessment intends to be inclusive in its approach to assess nature's contributions to a good quality of life, including not only different notions of what a good life entails, but also its linkages to patterns of inequality associated with changes in nature. **Table 1.1** presents a list of 14 categories of material and non-material indicators intended to capture the various aspects of GQL. These categories build upon and expand the categories used in the Millennium Ecosystem Assessment (2005), and are used throughout the present assessment, such as to discuss the implications of specific aspects of NCP, indicators of progress in societal goals (e.g., Aichi Biodiversity Targets, SDGs), implications of future scenarios to GQL, and the situation of IPLCs relative to other groups.

1.3.1.5 Institutions in the IPBES Conceptual Framework

The global assessment follows the widely accepted definition of institutions, understood as formal and informal rules and norms that structure individual and collective behaviour (Ostrom, 1990, 2005). In other words, institutions are collectively produced by actors and in turn shape their behaviour, stimulating, directing or restricting action (Giddens, 1986). The IPBES conceptual framework places institutions at the centre of our relationship to nature and biodiversity. This approach has helped to fill gaps in previous assessments, where the role of institutions at different societal levels was not elaborated. Institutions are the expression of the plurality of individual and collective practices underlying human individual and social behaviour towards each other and towards biodiversity and nature. Institutional arrangements act upon and mediate processes of natural resources claim and uses, and therefore the management of nature and biodiversity.

A variety of formal and informal institutional arrangements mediate interactions between our demand for a good quality of life and the pressures it puts on nature and biodiversity, and thus nature's contributions to people. Institutions as politically relevant social rules and norms can be thought of in terms of institutional orientations (e.g., social narratives, social expectations and behavioural norms, as well as social hierarchies and ascribed status), and allocative and distributive mechanisms (e.g., property systems and access rights to common and public goods, markets, formal and customary laws, policies including taxes, subsidies). Institutions are not equivalent to organizations, however the latter are composed of multiple institutions representing systems of rules and norms, for instance ministries, political parties, advisory boards, corporations, among others. Institutions also underlie, *inter alia*, investment initiatives and multilateral environmental and trade agreements, as well as their effects on other components of the conceptual framework.

As institutions emerge from interactions between people and social structures, they influence how decisions are taken and implemented, how power is exercised, and how responsibilities are distributed. Institutions determine to various degrees the access to, allocation and distribution of the various forms of resources and the benefits we derive from them. They can be organized along a

Table 1 1 **Material and non-material dimensions of a good quality of life (GQL) used across chapters of the global assessment.**

Adapted from the Millennium Ecosystem Assessment (2005).

GOOD QUALITY OF LIFE	DESCRIPTION
MATERIAL dimensions	
Food security	Involving components of knowledge, availability, access, utilization, stability, diversity and cultural preference
Water security	Involves quality, sufficiency, and access
Energy security	Involves availability, access and affordability without incurring health and physical risks
Shelter	Ability to live in a clean and safe shelter, reduce risk and vulnerability to hazards and stochastic events
Livelihood and income security	Ability to access resources, income necessary to fulfil material needs and social obligations, and pursue education, health, leisure, and work opportunities
Health	Including being nourished and functional, free of diseases, psychological satisfaction
NON-MATERIAL dimensions	
Good Social relationships	Including social cohesion, mutual respect, good gender and family relations, the ability to help others and provide for children, and the opportunity for active participation in one's society
Equity	Concerns evidence of parity in processes and outcomes across gender, age, race and ethnicity, income and other social indicators or dimensions of difference
Sense of cultural identity	Feeling of belonging to one or more social groups (as related for instance to locality, country, ethnicity, religion, activity, gender, generation), being respected for self-determination, practice of language, education and transmission, and ability to carry out activities related to intangible values and culturally valued means of existence
Personal and physical security	Including secure access to natural and other resources, safety of person and possessions, and socially equitable access to supporting systems and living conditions to be resilient to natural and human-caused disasters
Freedom of choice and action	Including having control over what happens and being able to achieve what a person values doing or being
Access to knowledge and education	Ability to pursue formal and informal education and knowledge in culturally appropriate languages, learning new skills, and accessing information necessary for participation in society and pursuit of culturally valued aspirations
Freedom to exercise spirituality	Ability to exercise one's faith, beliefs, and religious practices
Access to recreation and leisure	Ability to dedicate time to physical and psychological health, to have access to socially valued activities and spend time with family and friends
Enjoyment of natural beauty	Capacity to enjoy the beauty of nature, healthy and unpolluted landscapes and seascapes, also reflecting one's sense of place, artistic and spiritual inspiration, physical and emotional comfort

continuum of temporal and geographical scales spanning from the organizations of local groups and resource users to national governments to global institutions, such as in international treaties and policies or an intergovernmental platform such as IPBES. Also, at the global level, an international climate agreement for instance is an example of an institution that has both formal aspects (e.g., agreed emissions quotas) and informal aspects (e.g., a country's moral pledge). At all levels, institutions are expressed in the policies, property systems, the organization of markets, and the formal and informal agreements that create incentives and/or restrictions on our behaviours and attitudes towards nature. Institutions are thus behind the ways we monitor, control, reward and sanction behaviours, including defaulting to no action at all, e.g., the absence of a norm or rule regulating the use of a resource represents itself a mode of action.

The global assessment examines a plurality of institutional arrangements that have emerged within different contexts over the past 50 years to promote the sustainable management of nature and biodiversity and to address global problems such as climate change (Young, 2010). From local to global levels, chapters examine the ways institutions, for instance those related to conservation, are challenged by competing values and power dynamics, changing contexts and environmental conditions, its congruency with other institutions operating at intersecting social and ecological boundaries.

Consideration of formal and informal institutions in the global assessment is done in various ways depending on the focus of analysis, including how the respective institutions create and mediate particular drivers of change, their potential effectiveness or lack thereof in reducing the impact of drivers on nature and people, their short and long-term effectiveness in reaching goals in a cost effective and, not least, equitable manner, i.e., their effects on distribution of benefits and costs across individuals and groups within society. Another important aspect considered in institutional analyses in the global assessment relates to understanding how institutional arrangements interact, support and/or contract each other, and match or mismatch to ecosystem boundaries at different scales (Bodin, 2017; Brondizio *et al.*, 2009). Understanding the mismatches between institutional arrangements and ecosystems is particularly critical to understand social-ecological changes at regional and global scales. At these levels, common pool resource systems, such as a water, climate and atmosphere, the oceans, migratory species and other resources exhibit inherently emergent and transboundary properties, affected both by level-specific and cross-level institutions and decision-making, including distant drivers of change.

1.3.1.6 Direct and indirect drivers of change and their telecouplings

Within the global assessment we differentiate between indirect drivers (all anthropogenic in our framework), and direct divers (natural, anthropogenic, and natural-anthropogenic-interaction), and how they interact **(Box 1.2)**. Decisions such as macroeconomic policies implemented through formal institutions may not be the direct cause of a change in an ecological system but may have a direct influence on the direction and intensity of direct drivers of change such as land use, pollution, direct exploitation, and different manifestations of climate change. In turn, formal and informal institutions also mediate these interactions. The difference between direct and indirect drivers have important implication for policy considerations, i.e., while a direct driver can be addressed through more focused efforts and instruments, addressing indirect drivers may require more fundamental and systemic change.

Building upon previous efforts and typologies of drivers of change, the global assessment analyses drivers in two main ways: the analysis of direct and indirect drivers, and the analysis of their distant interactions, i.e., telecoupling. The first way in which drivers are analysed in this assessment is by the use of a common typology, applied consistently across chapters, although some variation in terminology is inevitable as the literature on the topic is diverse and continues to evolve (**Table 1.2**; Supplementary Material 1.3). Direct drivers have direct physical (e.g., mechanical, chemical, noise, light) impacts on nature and/or people. They are also sometimes referred to as 'pressures' (e.g., CBD, 2014; MA 2005) or 'proximate sources' (e.g., Lambin *et al.*, 1999, 2006; Turner *et al.*, 1990, in the literature in the context of other initiatives. According to the typology adopted by the global assessment, direct drivers include, *inter alia*, natural drivers such as eruptions and earthquakes, anthropogenic drivers such as pollution, land/sea use change, and direct exploitation and extraction of resources, and drivers that are derived from natural-anthropogenic interactions, such as different manifestations of climate change and invasive alien species (including zoonoses). Indirect drivers are drivers that operate diffusely by altering and influencing direct drivers. They do not impact nature directly, rather, they do it by affecting the level, direction, rate, and/or intensity of direct drivers. They have been referred to as 'underlying causes' or underlying 'driving forces' in the context of other initiatives (e.g., Lambin *et al.*, 1999; Maxim *et al.*, 2009). Both direct and indirect drivers can also affect other indirect drivers through different chains of relationship, varying in type, intensity, duration, and distance. These relationships can also lead to different types of spill-over effects (Liu *et al.*, 2013). Indirect drivers include institutions, economic, demographic, technological, governance, regional conflicts and wars, sociocultural and socio-psychological, and health related drivers. As discussed above, attention is given, among indirect drivers, to the role of institutions (both formal and informal) and impacts of the patterns of production, supply and consumption on nature, nature's contributions to people and to quality of life. Also, in the scenarios chapters (4 and 5), indirect drivers play an important role within the causal linkages to biodiversity and ecosystem change (IPBES, 2016b). Many global environmental scenarios are constructed on the basis of assumptions related to the development of these indirect drivers according to different storylines. Commonly, scenarios include indirect drivers such as model of economic development, demographic trends and factors, technological development, governance and institutions, and socio-cultural context. These analyses are developed on the basis of assumptions about how indirect drivers interact with current trends, providing the qualitative and (semi-) quantitative basis for models on the implications of direct drivers for nature, its contributions to people and to quality of life.

Drivers can be analysed from the perspective of distant influences and interdependencies, usually referred to as teleconnections and telecoupling, respectively (Friis *et al.*, 2016; Liu *et al.*, 2013, 2015). In the global assessment, the concept of 'telecoupling' is used to emphasize that human-nature interactions are interconnected through different chains of relationships, attributions, and impacts which may influence each other, varying according to type, intensity, duration, and distance of the interaction, and often exhibiting nonlinear patterns over space and time. Thus, telecoupling is used in the assessment as an umbrella concept encompassing processes that are distant not only

Table 1 2 **Typology of drivers used in the IPBES Global Assessment.**
See Supplementary Material 1.3 for a more detailed description.

DIRECT DRIVERS	**Natural**	Eruptions, earthquakes, natural climatic variability		
	Anthropogenic	Pollution (emissions, disposal, spill-overs, noise, others)		
		Land/sea use change	Transformations	
			Intensity changes	
		Direct disturbance, exploitation and extraction (of components of nature)		
	Natural-Anthropogenic (interaction)	Manifestation of climate change (e.g., changing temperature and precipitation, frequency and intensity of weather events, sea level change, ocean acidification)		
		Invasive alien species including zoonoses and pest outbreaks		
INDIRECT DRIVERS		Institutions (formal and informal)		
		Economic drivers	Patterns of supply	
			Patterns of production	
			Patterns of consumption	Economic affluence
				Inequality
				Poverty
		Demographic drivers		
		Technological drivers		
		Governance drivers		
		Conflicts and wars		
		Sociocultural and socio-psychological drivers (values, beliefs, norms, education)		
		Health problems as indirect drivers		

spatially but also in the temporal and functional senses. The term applies to a range of relevant phenomena related to nature, NCP and GQL, such as food trade impacts (Chaudhary & Kastner, 2016; Easter *et al.*, 2018; Sun *et al.*, 2017), food security (Nelson *et al.*, 2016), large-scale land acquisition (e.g., land-grabbing) (Rulli *et al.*, 2013), freshwater demand, and a variety of resource trades (Xiong *et al.*, 2018). Telecoupling approaches have been used to examine the relationship between resource demands and declines in biodiversity and ecosystem services, competition for water, the impact of tourism, processes of species invasion, the impact of foreign investment on the environment, the spread of diseases and connectivity of ecosystems, among others. In different parts of the assessment, authors use the perspective of telecoupling to examine ecological, physical, climatic and other natural telecouplings, as well as economic telecoupling such as trade and investments, sociocultural telecoupling such as in the circulation of expressive culture, symbols and narratives, and legal telecoupling, such as related to the impact of domestic regulations or international agreements on far-away areas and stakeholders. Global input-output (IO) analysis is used to quantify and qualify the economic interdependencies, such as to assess the trade and supply chains that connect primary producers and final consumers, often geographically far removed from each other.

1.3.2 Incorporating Indigenous and Local Knowledge and issues concerning Indigenous Peoples and Local Communities: a systematic and multi-facet approach

1.3.2.1 Defining and conceptualizing Indigenous Peoples and Local Communities, and Indigenous and Local Knowledge

Indigenous Peoples and Local Communities (IPLCs) is a term used internationally by representatives, organizations, and conventions to refer to individuals and communities who are, on the one hand, self-identified as indigenous and, on the other hand, are members of local communities that maintain inter-generational connection to place and nature through livelihood, cultural identity and worldviews, institutions and ecological knowledge. The term, as other similar regional terms, has gained usage in international forums during the past 2 decades. The term is not intended to ignore differences and diversity within and among Indigenous Peoples and between them and local communities. It is used largely to denote that there are communalities and shared concerns for Indigenous Peoples and Local Communities that are important to be represented in international forums, such as the CBD, IPCC, IPBES, among many others.

Indigenous and Local Knowledge (ILK) is a closely related term also widely used internationally and in published literature to refer to the worldviews, knowledge, practices, and innovations embedded in the relationship between people and nature, as expressed in local knowledge about the natural world, techniques and technologies of resource management, as well as in local institutions governing social relations and relationship to nature. Equivalent terms include Traditional Ecological Knowledge and Local Ecological Knowledge, among several others. ILK is understood as situated in place and social context, holistic but at the same time open and hybrid, continuously evolving through the combination of written, oral, tacit, practical, and scientific knowledge attained from various sources, validated by experimentation and in practice of direct interaction with nature. As IPLCs are confronting pressures and undergoing sociodemographic, cultural, economic changes worldwide, inter-generational transmission of ILK is declining fast in many regions of the world (e.g., Turnbull, 2009).

Both terms, IPLCs and ILK, are used as umbrella terms to represent the most culturally diverse segment of the world's population, which in spite of such diversity, share many common concerns (see section 1.3.2.2). The global diversity of IPLCs –cultural and historical, social and political, economic and environmental– defy a common definition for the term as a whole and for each of its two components. While the United Nations has recognized and used multiple criteria to define 'Indigenous Peoples', including ancestry, distinct cultural features such as language, religion, membership in tribal systems, material culture, cosmology, livelihood, origin and residence, among others, no common definition has been adopted internationally. Instead, the United Nations, as many countries, have increasingly adopted self-identification, by individuals and their acceptance by a community, as a primary criterion. Likewise, no single definition of 'local communities' is internationally accepted. In the CBD, as other international platforms such as IPBES and IPCC, local communities are recognized for their diversity, yet having historical linkages to place and natural resources, their multiple domains of ecological knowledge, dynamic and hybrid resource management techniques and technologies, their customary and formal institutions to manage natural resources, their diverse worldviews and forms of relationship to nature.

In the absence of a comprehensive general definition of IPLCs, authors of the global assessment were particularly concerned with recognizing intra- and inter-regional differences in definitions regarding IPLCs and ILK. Many Indigenous Peoples and Local Communities are not recognized as such, or at all, by their respective countries or in the literature. For historical, political and language reasons, some groups are highly visible and others invisible to policymakers, scholars, society, and even representatives of IPLCs. For these and other reasons, authors of the global assessment were sensitive to the fact that definitions of ILK and IPLCs are context-specific and should be recognized as such, and as inclusive as possible when evaluating data and literature. The operational strategy developed to include ILK and IPLCs in the assessment recognizes the criteria of self-identification and self-determination for IPLCs.

Table 1.3 shows 15 dimensions used as a reference to contextualize the diversity of IPLCs around the world. In practical terms, this meant maintaining literature review data disaggregated to allow different interpretations of whom to include as IPLCs and what as ILK. Likewise, as expressed in the questions guiding the work on ILK and IPLCs in the assessment (**Box 1.3** and Supplementary Material 1.4), we have placed a particular emphasis on the relationship between knowledge, practice, and innovations. As such, these guiding questions are intended to highlight that irrespective of cultural differences, importance was given to assessing the contributions of IPLCs to the stewardship and management of nature, and its contributions locally and to the larger society, without romanticizing ILK. Literature review and dialogue workshops also allowed authors to assess the pressures experienced by IPLCs in different parts of the world as well as relevant policy options and instruments concerning, directly or indirectly, IPLCs.

It is important to note that many groups of farmers, ranchers, pastoralists, fishers, and foresters who also have multi-generational roots in place, close connection to nature, and directly contribute to the management and conservation of biodiversity, may not be included, for multiple reasons, as belonging to the broader category of IPLCs. Independently, authors of the assessment have also used and included literature regarding the management and conservation practices found in regions around the world.

Estimates suggest that Indigenous Peoples (IP) include some 5000 groups, comprising between 300–370 million people (Hall & Patrinos, 2012), ranging from isolated groups to large populations across most regions of the planet, including in urban centres. Local Communities (LC) on

Table 1 3 **Recognizing the global diversity of Indigenous Peoples and Local Communities.**

DIMENSIONS	GRADIENT OF CONDITIONS		
1. Demography	Small population	⟷	Large population
2. Social identity	Unrecognized	⟷	Formal
3. Language	Endangered	⟷	Expanding
4. Environment relationship	Continuous, inter-dependent	⟷	Sporadic/aesthetic/specialized
5. Land/territorial security	Informal/contested	⟷	Formal/recognized
6. Economic relations	Self-sufficiency, reciprocity	⟷	Market, trade
7. Property system	Open, common	⟷	Private, dispossessed
8. Technology use	Local techniques	⟷	Conventional, energy-intensive
9. Knowledge base, transmission	Oral/culturally coded	⟷	Recorded
10. Urban relationships	Distant	⟷	Inter-dependent
11. Socio-economic conditions	Poverty	⟷	Security
12. Security, pressures	Low	⟷	High
13. External dependency	Self-sufficient	⟷	Aid-dependent
14. Existence and Persistence	Millennia	⟷	Decades to centuries
15. Degree of self-governance	Autonomy and sovereign rights	⟷	External control

the other hand involve an even larger, and equally diverse population ranging from communities in peri-urban and coastal zones to rural communities isolated from urban centres inhabiting sparsely populated landscapes, coastal areas, and small towns around the world (see **Box 1.4**). While representing large sectors of the rural population in developing countries, they also represent important segments of the population in developed countries, producing diverse food and products, managing cultural and production landscapes, safeguarding agrobiodiversity and the genetic diversity of domesticated animals, and carrying the know-how of material culture and technology, food cultures and medicines and associated intangible heritage. As the application of the term may vary according to national or regional context, there are no clear ways to estimate the world population that could be classified as local communities. Proxy estimates based on factors such as distribution of smallholders in rural areas and land managed under customary rights would suggest a population around well above 1 billion people **(Box 1.4)**. They include micro-, small- and medium-scale farmers, herders and pastoralists, fishers, extractors and foragers, foresters and agroforesters managing a significant portion of the world's terrestrial and coastal landscapes and biodiversity.

In some regions, the IPLCs experience marginalized socioeconomic conditions. Many IPLCs share conditions of poverty, experience violence, have limited access rights to land and resource, and lack of access to conventional and to culturally sensitive health care systems. They also lack access to education appropriate to local culture, as well as public services such as water, energy, and sanitation (Ding *et al.*, 2016; Hall & Patrinos, 2012; Pearce, 2016; Romanelli *et al.*, 2015). Throughout the world, the IPLCs experience contestation of customary rights, physical and legal conflicts with mining companies, large-scale agriculture, forest companies, multinational oil corporations, as well as displacement associated with these pressures, from migration to government development programs. On the other hand, as the chapters of the assessment show, a multitude of examples exist of IPLCs leading innovation and collaborative efforts to manage and conserve nature, implement sustainable management practices, and find solutions to local problems.

Box 1 3 Global estimation of lands held and/or managed by Indigenous Peoples and Local Communities and 'counter-mapping' efforts.

The lands held in rights and/or managed by Indigenous Peoples and Local Communities (IPLCs) are found in all inhabited regions of the world (Dubertret & Alden Wily, 2015). It is estimated that between half and two-thirds of the world's lands are under customary tenure or community-based regimes, mostly held by IPLCs (Alden Wily, 2011). Estimates suggest that customary tenure, a significant portion of which overlap with different types of government, corporate, and/or private control, may extend to over 8.54 billion hectares or around 65% of the global land area inhabited by around 1.5 billion people (Alden Wily, 2011). Among them, between 300 and 370 million self-identify as Indigenous Peoples, who currently inhabit and manage around 28% of the global land area (Nakashima *et al.*, 2012; Garnett *et al.*, 2018). Pastoralists and agropastoralists, estimated to represent around 120 million people at the global level, move over larger areas and across altitudes within and beyond borders and across land held in different types of customary rights, often following pathways with long histories of transhumance (Rass, 2006). Still, only 10% of the world's land are formally recognized as indigenous and/or community lands (Rights and Resources Initiative, 2015). There are no global estimates available for the customary rights of IPLCs in freshwater and marine systems.

While representing the most up-to-date evaluation of IPLC lands globally, these estimates are limited by both the lack of visibility of IPLC lands in many regions and limited data. About 70% of land properties in low-incoming countries are unregistered (McDermott *et al.*, 2015), and 90% of Africa's rural land is estimated to be not formally documented (Byamugisha, 2013). Even when land titles have been issued to communities, relevant data and statistics regarding them may not be produced, such as in Peru where IPLC lands are not included in the official cadastral records, although communities have legal ownership rights over a third of the country's land area (IBC, 2016). However, decades of "counter-mapping" are progressively contributing to fill this lack of information: an ever-increasing number of maps are produced by and for IPLCs in all parts of the world, often used as means to depict the lands and resources they hold and use for asserting their customary land rights (e.g., Peluso, 1995). Local, national, or regional geographic platforms giving visibility to these maps multiply quickly[6]. For instance, the LandMark initiative (LandMark, 2018), has been scaling up these efforts by providing a global picture of IPLC lands, but, although more than a million maps covering 11.2% of the world's land have already been gathered on the platform, it is still far from complete. The existing geographic information on the matter is often scattered in many communities and organizations, some may see more harm than good in publishing politically sensitive IPLC land claims, and a large part of the world's IPLC lands are yet to be mapped. In another effort, using published open access data sources, Garnett *et al.* (2018) aggregated maps of indigenous lands for 87 countries. Another example is the Indigenous and Community Conserved Areas registry (ICCA Registry) has been instituted since 2009 through UN institutions, IUCN, the ICCA Consortium and additional partners to appropriately recognize the conservation and livelihoods role of IPLCs. While much has to be done to clarify the cartography of IPLC lands, ongoing efforts to fill critical gaps in information on the location and extent of indigenous and community lands has gained an important momentum (Corrigan *et al.*, 2016). Geospatial data integration, satellite monitoring, participatory mapping and transparency of information are increasingly playing a role in strengthening the tenure security of indigenous and community lands (Di Gessa, 2008).

1.3.2.2 Scaling-up the analysis of contributions of Indigenous Peoples and Local Communities to biodiversity management, conservation, and regional economies

Recognition and documentation of indigenous and local ecological knowledge, practices, and innovations (ILK) of Indigenous Peoples and Local Communities (IPLCs) show that they date back millennia, always evolving in dynamic and adaptive ways. They have been recorded in oral history and accounts in written texts such as large non-conventional scholarly texts of medical systems (e.g., Chinese or ayurvedic medicines), diverse art forms, popular literature, and various types of reports (Motte-Florac *et al.*, 2012). Oral histories, storytelling, songs and poems, objects and artifacts continue to be powerful and as relevant today as forms of knowledge transmission. In 2015, for instance, Australian researchers showed that Aboriginal memory regarding coastal inundation in Australia could be traced to over 7000 years (Nunn & Reid, 2016).

Today, evidence shows that IPLCs have shaped the ecologies and resource economies of vast regions of the world, from managing forests, soil fertility, grasslands, mountains, watersheds, and coastal areas to the cultivation and nurturing of domesticated and wild species and the management of vast social-ecological production landscapes for humans and non-humans. Such knowledge forms the basis of traditional medicines and modern pharmacological compounds, the foundational genetic basis of local and global crops, domesticated animals and an array of microorganisms used for making

6. Among many examples, see http://tierrasindigenas.org/ for Paraguay, https://raisg.socioambiental.org/ for the Amazon, www.mappingforrights.org/ for the Congo Basin, etc.

bread, cheese, preserves, and beverages. Currently, IPLCs manage, under various property regimes, a high proportion of global terrestrial and biodiversity rich landscapes, and a significant portion of coastal areas, and transboundary watersheds. Land managed by Indigenous Peoples alone cover at least ~38 million km^2 in 87 countries on all inhabited continents. This represents over a quarter of the world's land surface and intersects about 40% of all terrestrial protected areas and ecologically intact landscapes (Garnett *et al.*, 2018).

While local in action, IPLC management of nature provides contributions to the larger society, in rural and urban areas alike, including the provisioning of food, fibers, material, and medicine to local and to export markets, and the management of agrobiodiversity of major regional and global crops. In many regions IPLC lands contribute to the conservation of watersheds that supply large regional populations. Increasingly, scientific research and reports recognize the central role played by IPLCs to advance climate change mitigation initiatives and for the implementation of CBD's Strategic Plan for Biodiversity 2011–2020 and the 2050 Vision. Similarly, there is a wide body of evidence documenting the impact of economic development and cultural/social change on IPLCs, impacts that have accelerated since the 1970s and continue to do so in many regions.

While evidence on these contributions and transformations is robust, it is still regionally dispersed and includes significant gaps at the global level. The global assessment builds on previous and ongoing efforts to contribute to bridge these gaps through knowledge syntheses and integration and systematic literature reviews, the use of available geospatial data, online and face-to-face consultations with IPLC representatives and experts on indigenous and local knowledge and issues. Bringing together representatives of and experts on indigenous and local knowledge and issues in dialogue workshops, and producing synthetic reports, has helped in particular to identify commonalities among IPLCs across regions, specifically related to drivers of changes affecting them. Likewise, synthesis and upscaling has been facilitated through the examination of common themes, such as agrobiodiversity, local indicators of environmental change, protected areas, climate change mitigation, among others; themes which are relevant from local to global levels.

The global assessment builds upon a long history of efforts. Since the 1950s, numerous international efforts have emerged to recognize the rights and the knowledge of Indigenous Peoples in particular, including the Indigenous and Tribal Populations Convention of 1957, first international convention for the protection of Indigenous Peoples, and put forward by the International Labour Organization (ILO). In the early 1980s, the United Nations Economic and Social Council (ECOSOC) created the Working Group on Indigenous Populations (WGIP) and in 2000 established the United Nations Permanent Forum on Indigenous Issues (UNPFII), a body which continues to grow in scope and influence (also referred as United Nations Permanent Forum on Indigenous Peoples – UNPFIP). By 1989, a landmark international convention, the Indigenous and Tribal Peoples Convention or ILO Convention 169, advanced the original 1957 ILO convention. Finally, in 2007, after two decades of negotiations, the United Nations adopted the Declaration on the Rights of Indigenous Peoples. In spite of representing major advances, these conventions and declarations have not been without contestation and controversies, including on the definition and recognition of Indigenous Peoples in different parts of the world.

Along with growing concerns on environmental deterioration and human rights, and interest in locally developed and alternative approaches to managing the environment since the 1980s, attention has expanded to include a wide range of local communities, including forest peoples, farmers, fishers, herders, pastoralists, diversely manifested around the world. In many regions of the world, Indigenous Peoples and Local Communities joined forces with scientists, artists, civil organizations, and policymakers to raise attention to the interlocked plight of IPLCs and environmental degradation, progressively recognizing the distinct contributions to the larger society, including to international agreements on biodiversity conservation, sustainable development, and climate change. This expanded attention to local communities was already captured in the establishment of the Convention of Biological Diversity (CBD) in 1992, in particular the provision under Article 8(j) pertaining to IPLCs. Along with the efforts mentioned above, the CBD article 8(j) represented a watershed moment for the recognition of the knowledge, practices, and concerns of IPLCs, one that continues to grow today[7]. As part of this process, IPLC networks have expanded and are becoming increasingly instrumental in linking local to global concerns and voices of IPLCs.

The systematic inclusion of ILK and issues concerning IPLCs in global-scale assessments have been limited or at best based on case studies; however, they have been central to advance both understanding and the participation of IPLCs in such efforts. For instance, in 1999 UNEP published "Cultural and Spiritual Values of Biodiversity" as a complementary contribution to the First Global Biodiversity Outlook (UNEP, 1999). The Millennium Ecosystem

7. Article 8(j) has been a catalyst for advancing understanding and action to 'respect, preserve and maintain the knowledge, innovations and practices of Indigenous Peoples and Local Communities relevant for the conservation of biological diversity and to promote their wider application with the approval of knowledge holders and to encourage equitable sharing of benefits arising out of the use of biological diversity.' (CBD Working Group on Article 8(j)). https://www.cbd.int/convention/wg8j.shtml. Accessed April 2, 2018.

Assessment, published in 2005, included sections dedicated to ILK and IPLCs, particularly within its chapters related to 'cultural ecosystem services'. A rich array of regional assessments and syntheses has been developed, while focusing on different themes and issues. For instance, the Arctic Biodiversity Assessment (CAFF, 2013) prepared by the working group Conservation of Arctic Flora and Fauna (CAFF) of the Artic Council examined issues related to Indigenous Peoples and biodiversity in the Arctic including oral histories and other types of evidence on traditional ecological knowledge[8] (TEK).

During the last 20 years, international agencies under the United Nations, the World Bank, Consortium of International Agricultural Research Centres (CGIAR) research centres, and numerous Non-Governmental Organizations have published regional and global reports on various issues of concern to IPLCs. In parallel to these efforts, academic and non-academic literature dedicated to ILK and to issues of concern to IPLCs have expanded exponentially, increasingly written with and by representatives of IPLCs. Of particular relevance in recent years were the efforts carried out by organizations representing IPLCs in the CBD and other forums. A notable example was the publication in 2016 of the report *Local Biodiversity Outlooks: Indigenous Peoples' and Local Communities' Contribution to the Implementation of the Strategic Plan for Biodiversity 2011–2020* (FPP *et al.*, 2016) developed by the Indigenous Network of the Convention on Biological Diversity. The coverage of IPLCs and ILK in reports of the Intergovernmental Panel on Climate Change (IPCC), while limited, has also been progressively increasing (Ford *et al.*, 2016).

The establishment of IPBES' first work programme in 2012 represented a landmark in institutionalizing the inclusion of ILK in global and regional level assessments. The approval of IPBES' culturally-inclusive conceptual framework and related analytical tools (such as on nature's contributions to people and multiple values of nature), provided the foundation to include ILK as part of the IPBES's assessments on pollination, land degradation and restoration, and the four regional assessments covering the Americas, Europe and Central Asia, Africa, and the Asia-Pacific region. These assessments also contributed to advance mechanisms for consultation with IPLC representatives, such as through the organization of dialogue workshops incorporated as part of the assessment process. From the onset, IPBES formed a Task Force on ILK dedicated to developing guidelines for integrating ILK in IPBES activities. This task force is currently involved in developing a participatory mechanism that contributes to expand the participation of IPLC-based networks.

8. Other terms often used interchangeably with ILK include Local and Indigenous Knowledge Systems (LINKS), Traditional Ecological Knowledge (TEK), among others.

Table 1 4 **Operationalization strategy for systematically including Indigenous and Local Knowledge (ILK) and issues of concern to Indigenous Peoples and Local Communities (IPLCs) in the global assessment.**

i. Question- based approach	Three overarching questions and 36 chapter-specific questions were developed to guide authors in literature review and to guide consultations and dialogues activities.	**Inclusive definition of IPLCs and ILK**
ii. Systematic and inclusive review of published evidence and geospatial data	The global assessment integrates evidences from multiple sources. 1) systematic literature search in indexed journals and search engines; 2) information from other IPBES assessments and proceedings of earlier ILK Dialogue Workshops; 3) geospatial data from international research centres and national institutions; 4) information derived from an on-line 'Call for Contribution' platform developed specifically for the global assessment; and, (5) inputs received from face-to-face presentations and consultations with IPLC networks and organizations. The chapters include over 3000 bibliographic references, including articles, books, and reports, relevant to ILK and IPLC issues.	
iii. Author's Liaison group	28 authors (Coordinating Lead Authors and Lead Authors) and 32 Contributing Authors directly participated in the analysis of evidence of literature on ILK/IPLCs. Several authors participated in dialogue and consultation workshops	
iv. Online Call for Contributions	An international Online Call for Contributions was carried out between August and December 2017 receiving 363 contributors from over 60 countries and providing over 1200 bibliographic resources.	
v. Face-to-face consultation and dialogues	Multiple forms of dialogues and consultations with representatives of IPLCs and the scientific community were carried out in international fora and community grounds involving representatives of Indigenous Peoples and Local Communities, experts and practitioners. These include: UN Permanent Forum on Indigenous Issues, USA, 2017, 2018; Dialogue on Human rights and Conservation, Kenya, 2017; Society of Ethnobiology, Canada, 2017; Arctic Dialogue, Finland, 2018; CBD: SBSTTA and 8j, Canada, 2017; Communities, Conservation and Livelihoods Conference, CCRN-IUCN, Canada, 2018; International Society of Ethnobiology, Brazil, 2018.	

Implementing an operational strategy for ILK and IPLCs in the global assessment: The global assessment builds upon these efforts to accomplish its mandate to include ILK and issues of concern to IPLCs as an integral part of the assessment process. To accomplish these goals, a scoping document and an operationalization strategy dedicated to IPLCs and ILK was developed at the onset, discussed and reviewed by multiple constituencies within IPBES and in dialogues with experts and IPLC representatives. This operationalization strategy was used to guide authors to coordinate activities within and across chapters. **Table 1.4** presents a synthesis of the scoping and operationalization strategy for the inclusion of ILK and IPLCs in the global assessment. This strategy includes five main components (see Supplementary Material 1.4): i. A question-based approach **(Box 1.4)**; ii. Systematic and inclusive review of published evidence and geospatial data; iii. A dedicated ILK liaison authors' group; iv. Online Call for Contributions; and, v. Dialogue and consultation with representatives of IPLCs and experts.

This strategy, particularly the detailed set of questions guiding this component within each chapter, set forward an ambitious agenda for synthesis and reflection on issues related to topics of concern to IPLCs and the contributions of their knowledge and practices to nature and its contributions to people. Because of data gaps and difficulties in integrating data from different parts of the world, languages, and representing different knowledge systems, responding to some questions has been challenging and, in some cases, only limited advances were possible. Consultation and dialogue workshops were organized and carried out in fora where representatives and experts from various regions and stakeholder groups could come together. The global assessment is also intended to help identify knowledge gaps, therefore the efforts presented here are also meant to encourage and stimulate research groups and practitioners working on different aspects of ILK and IPLCs, at different levels and regions, to carry out research and synthesis to inform future assessments.

1.3.3 Scenarios of future change

Two chapters of the global assessment review future scenarios and possible pathways to achieve them and consider the implications of achieving or missing of internationally agreed goals such as the Aichi Biodiversity Targets and the SDGs. In chapter 4, scenarios are used to explore a range of plausible futures, based on potential trajectories of direct and indirect drivers. Chapter 5, on the other hand, evaluates pathways and policy intervention scenarios in order to achieve desirable futures, paying particular attention to the interactions of various SDGs

Box 1 4 ILK/IPLCs Guiding Questions for the Global Assessment.

A question-based approach provided a common reference for authors to review empirical evidence and as a basis for consultations and dialogues activities. Three overarching questions were developed within the scope and mandate of assessment, which were then further detailed into 36 chapter-specific questions used to guide the work of chapters 2 to 6.

1. *'What have been the contributions of indigenous and local knowledge (ILK), practices, and innovations to the sustainable use, management and conservation of nature and nature's contributions to people at regional and global scales?*

   This question is based on accumulated evidence indicating that while knowledge, practices, and innovations of IPLCs related to nature are locally based, they are manifested in regional landscapes and ecosystems, and are globally relevant.

2. *'What are the most important features, pressures and factors related to and/or enabling or constraining these contributions, as well as impacting present and future quality of life of IPLCs?'*

   This question is based on accumulated evidence indicating that in many regions IPLCs are at the forefront of social, economic, political and environmental/ecological pressures that directly affect the environment; they are socially and economically marginalized and are experiencing high rates of social and environmental changes.

3. *'What policy responses, measures, and processes can contribute to strengthen and improve the institutions and governance of nature and its contributions to people with regard to IPLCs?'*

   This question is based on accumulated evidence recognizing an important role for IPLCs in supporting the global biodiversity strategy pre- and post-2020, the 2030 Sustainable Development Goals, and climate mitigation goals in the Paris Agreement on Climate.

Thirty-six chapter-specific questions are available in Supplementary Material 1.4. They include questions related to the management of landscapes, ecosystems and watershed, species diversity, agrobiodiversity, protected areas, institutions and customary systems, drivers of environmental and social change, climate change impacts and adaptation, the contributions of IPLCs to international conventions, among several others.

between now and 2050 (SDGs, 2050 Vision). The objective is to facilitate a better understanding of the types of socio-economic development pathways leading to outcomes that are closest or furthest to these goals. This complementarity between scenarios and pathways in the context of the IPBES conceptual framework and the global assessment is illustrated in **Figure 1.4 and Figure 1.6**.

In chapter 4, four main types of scenarios are distinguished: exploratory, target-seeking, policy screening, and retrospective policy evaluation **(Figure 1.6)**. The chapter focuses on exploratory scenarios, which assume the absence of explicit policy intervention, and often combine extrapolations of past trends with new assumptions. Exploratory scenarios are often developed using participatory methods and can be either qualitative, often in the form of storylines, or quantitative, often in the form of models (van Vliet & Kok, 2013). Some groups of scenarios developed in the last few decades share many aspects of their storylines and are considered here as "archetype scenarios"; these archetypes vary mainly in the degree of dominance of markets, globalization, and policies toward sustainability. Chapter 4 follows the IPBES methodological assessment on scenarios and models (IPBES, 2016b) for the adoption of 'scenario families' (van Vuuren *et al.*, 2012), also covering archetypes based on scenarios developed by the Global Scenarios Group (GSG) (Hunt *et al.*, 2012; Raskin, 2005). The scenarios analysed include those that are often restricted to particular temporal or spatial scales and limited in scope and incomplete regarding quantitative information about nature, ecosystem services, and quality of life. Although recent advances in integrated assessment modelling seek to overcome these restrictions (e.g., Harfoot *et al.*, 2014), important gaps related to conservation of biodiversity remain in global scenarios, such as integrated scenarios for vulnerable areas, and socioeconomic scenarios developed for and in collaboration with IPLCs (Furgal & Seguin, 2006).

In order to design the means of achieving international biodiversity targets and development goals, and to assess the role of biodiversity and ecosystems in achieving the SDGs, Chapter 5 examines recent knowledge about target-seeking or normative scenarios relating to nature, nature's contributions, and quality of life, and their interlinkages. The chapter focuses on both the quantitative aspect of scenarios, i.e., technical options, and their qualitative assumptions, i.e., how change will be addressed in terms of values, institutions and governance. In that sense, scenarios are viewed as plausible and relevant narratives about the future in the frame of major uncertainty, rather than forecasts or predictions (Ferrier *et al.*, 2016; Raskin, 2005). A clear distinction is made between the terms 'scenarios' and 'pathways'; while scenarios use narratives to explain outcomes generated by a model, pathways are possible trajectories toward the achievement of specific outcomes, for instance biodiversity conservation goals and targets in the context of the SDGs. Multiple scenario studies are combined here to inform such pathways, and three backbone angles are considered: a) different types of scenarios as developed in Chapter 4 (target-seeking, sustainability-oriented i.e., global and regional sustainability archetypes, and some policy-screening scenarios), b) a cross-scale focus (global to local as fine spatial resolutions provide contextual insights that global scenarios alone may not capture), and c) a nexus approach based on clusters of SDGs and complemented by relevant literature. Building on the IPBES regional assessments meta-analyses, Chapter 5 also seeks to give emphasis on local and participatory scenarios, especially visions based on ILK, highlighting how interactions between spatial and temporal scales are relevant for future pathways.

Scenarios, as a way of thinking critically about the future of nature and NCP, have the potential to feed major phases of decision-making in the policy cycle, from agenda setting and design to implementation and review. Accordingly, chapters 4 and 5 provide important elements for chapter 6 on policy options **(Figure 1.6)**. Policy and decision-making processes rely on estimates of anticipated future socio-economic pathways, and on knowledge of the potential outcomes of actions across distinct geographic regions, scales, sectors and social groups, especially in the face of high uncertainty and unpredictability (Peterson *et al.*, 2003). In the IPBES context, scenarios and models play complementary roles in describing possible futures for drivers of change or policy interventions and translating those scenarios into projected consequences for nature and its contributions to people (IPBES, 2016b)

1.3.4 Units of analysis

The subdivision of the Earth's surface into spatial units for the purpose of analysis is notoriously controversial and there is no single agreed-upon system that IPBES can adopt as its standard. The global assessment thus adopts the term 'Units of Analysis' also used in other IPBES assessments. The term Units of Analysis refers to a broad-based classification system at the global level, considering both the state of nature in classes equivalent to what is commonly called 'biomes' or 'ecoregions', and classes where ecosystem structure and function have been severely altered through human management, which can be called 'anthromes' or anthropogenic environments (Ellis & Ramankutty, 2008).

The classification of Units of Analysis was developed over several years of consultations with experts involved in various IPBES regional and thematic assessments as well as the global assessment. The current Units of Analysis took into account previous classifications of biomes, ecoregions

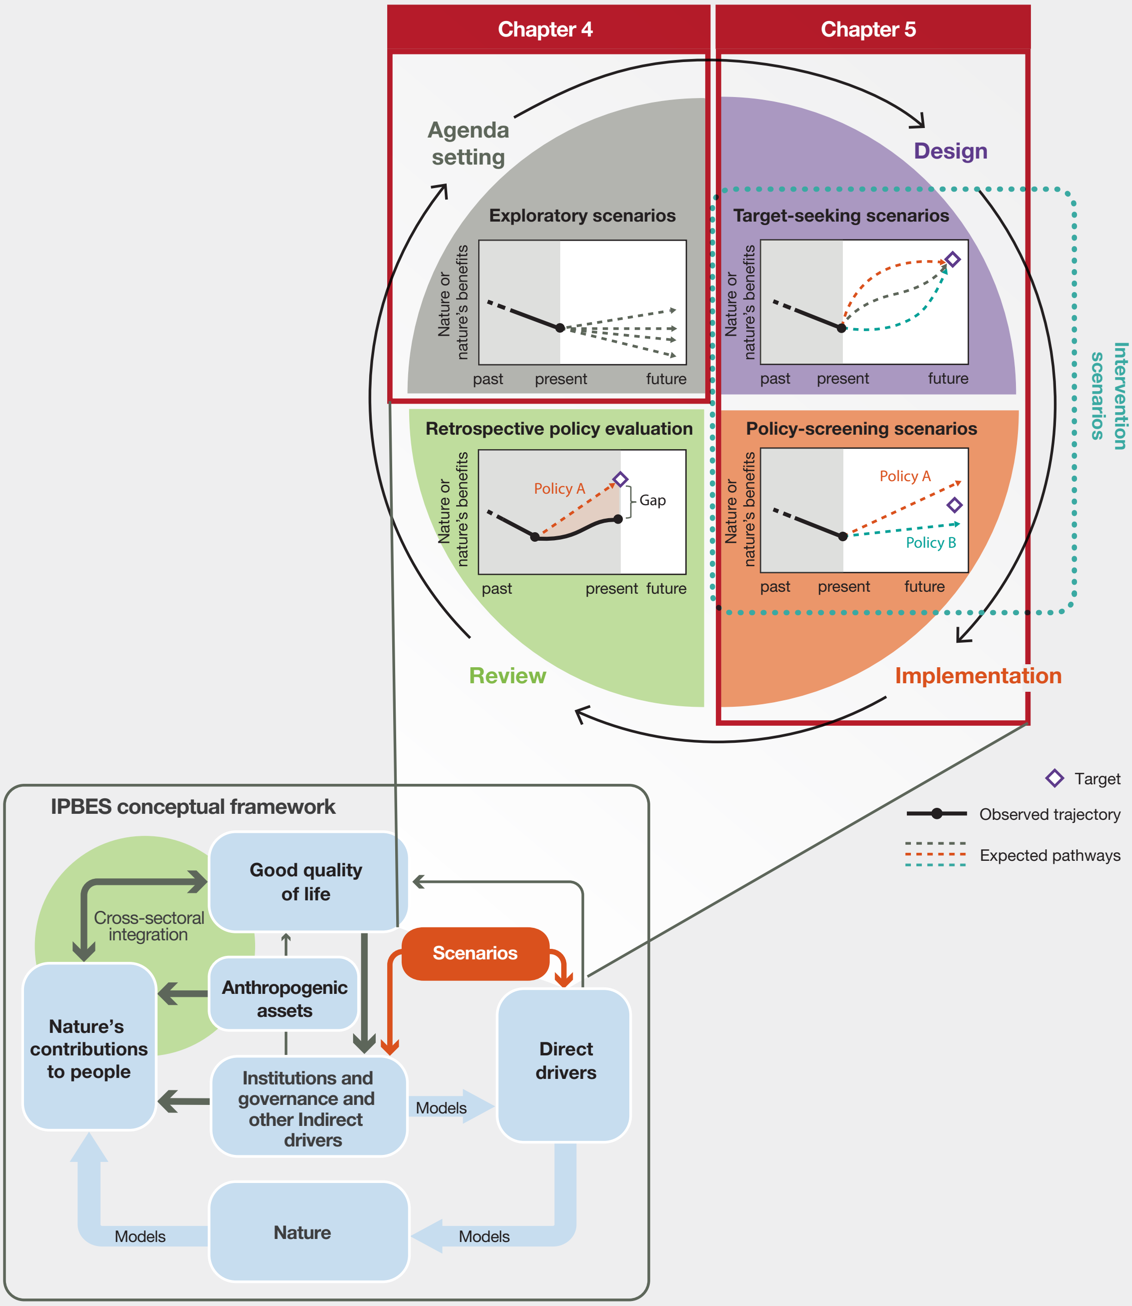

Figure 1 6 **Scenarios in the Global Assessment.**

The right-hand side of the figure shows what Chapters 4 and 5 assessed in terms different types of scenarios within major phases of the policy cycle. The left-hand side of the figure shows the relationships between scenarios (burgundy arrows), models (blue arrows) and the key elements of the IPBES conceptual framework. This figure was modified from the Summary for policymakers of the methodological assessment of scenarios and models of biodiversity and ecosystem services of the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES 2016b).

(Olson *et al.*, 2001; WWF, 2018), Millennium Ecosystem Assessment reporting categories (MA, 2005) and regional habitat classifications (i.e., European nature information system, EUNIS; EEA, 2018). The goal of the Units of Analysis is to serve the needs of the coarse level of global analysis, reporting and communication in a policy context. Given differences among regions and the needs of regional assessments, this list of global units may not match the regional units.

#	UNIT OF ANALYSIS	TERRESTRIAL	FRESH-WATER	MARINE	HUMAN
1	Tropical/subtropical forests	xxx			
2	Temperate/boreal forests/woodlands	xxx			
3	Mediterranean	xxx			
4	Arctic and mountain tundra	xxx			
5	Tropical/subtropical grasslands	xxx			
6	Temperate grasslands	xxx			
7	Deserts and xeric shrublands	xxx			
11	Cryosphere	xx	x	x	
8	Wetlands		xxx		
13	Inland waters		xxx		
14	Shelf ecosystems			xxx	
15	Surface open ocean			xxx	
16	Deep sea			xxx	
9	Urban/Semi-urban	..	..		xxx
10	Cultivated areas	..	..		xxx
12	Aquaculture	..	..	..	xxx
17	Intensive/multiple use coastal areas	..	..	..	xxx
		8	2	3	4

The list of 17 global Units of Analysis includes 13 biomes, and 4 anthromes **(Figure 1.7)**. Of the 13 biomes, 7 are terrestrial, 2 are freshwater, 3 are marine and one cuts across all three. The four anthromes include 2 exclusively terrestrial ones, where ecosystem function is transformed to a very high degree from natural pathways to human ones – urban/semi-urban areas and cultivated areas. The aquaculture anthrome mirrors 'cultivated areas' but may be derived from terrestrial, freshwater or marine biomes. Finally, the 'intensely and multiply used coastal' anthrome reflects the unique position of the coastline and our use of it, sandwiched between land and sea and a nexus for terrestrial, marine, freshwater and climatic processes. The anthromes layer over biome units (e.g., a city in a grassland area) but are so transformed that the original biome may no longer exist there.

Definitions for each unit are given in Supplementary Material 1.5 and defined and examined more fully in Chapter 2.2 (Nature). They combine standard definitions (such as from existing biome classifications) and operational elements to cope with variation over the globe and data limitations for mapping and determining their precise boundaries.

1.3.5 Use of Indicators

The global assessment adopted a multi-dimensional system of indicators to examine status and trends, progress towards international goals such as the Aichi Biodiversity Targets and the SDGs, evaluate policy instruments, and consider plausible future scenarios. Indicators are considered synthetic forms of data, information, and knowledge that are harmonized to help understand the status, cause or outcome of an object or process both quantitatively and qualitatively. In other words, indicators are measures of different aspects of nature that help monitor, compare and communicate changes in the state of nature over time. Indicators have advantages and limitations depending on the scale of aggregation and/or how complex is the phenomena an indicator aims at expressing. Indicators are best seen as nested and can range from directly measurable parameters that are included in monitoring to aggregated indices. Standardized indicators are of great importance for assessments because they provide a common set of categories and common language to talk about status and trends in nature, thus providing common threads and quantitative points of comparison from which expert

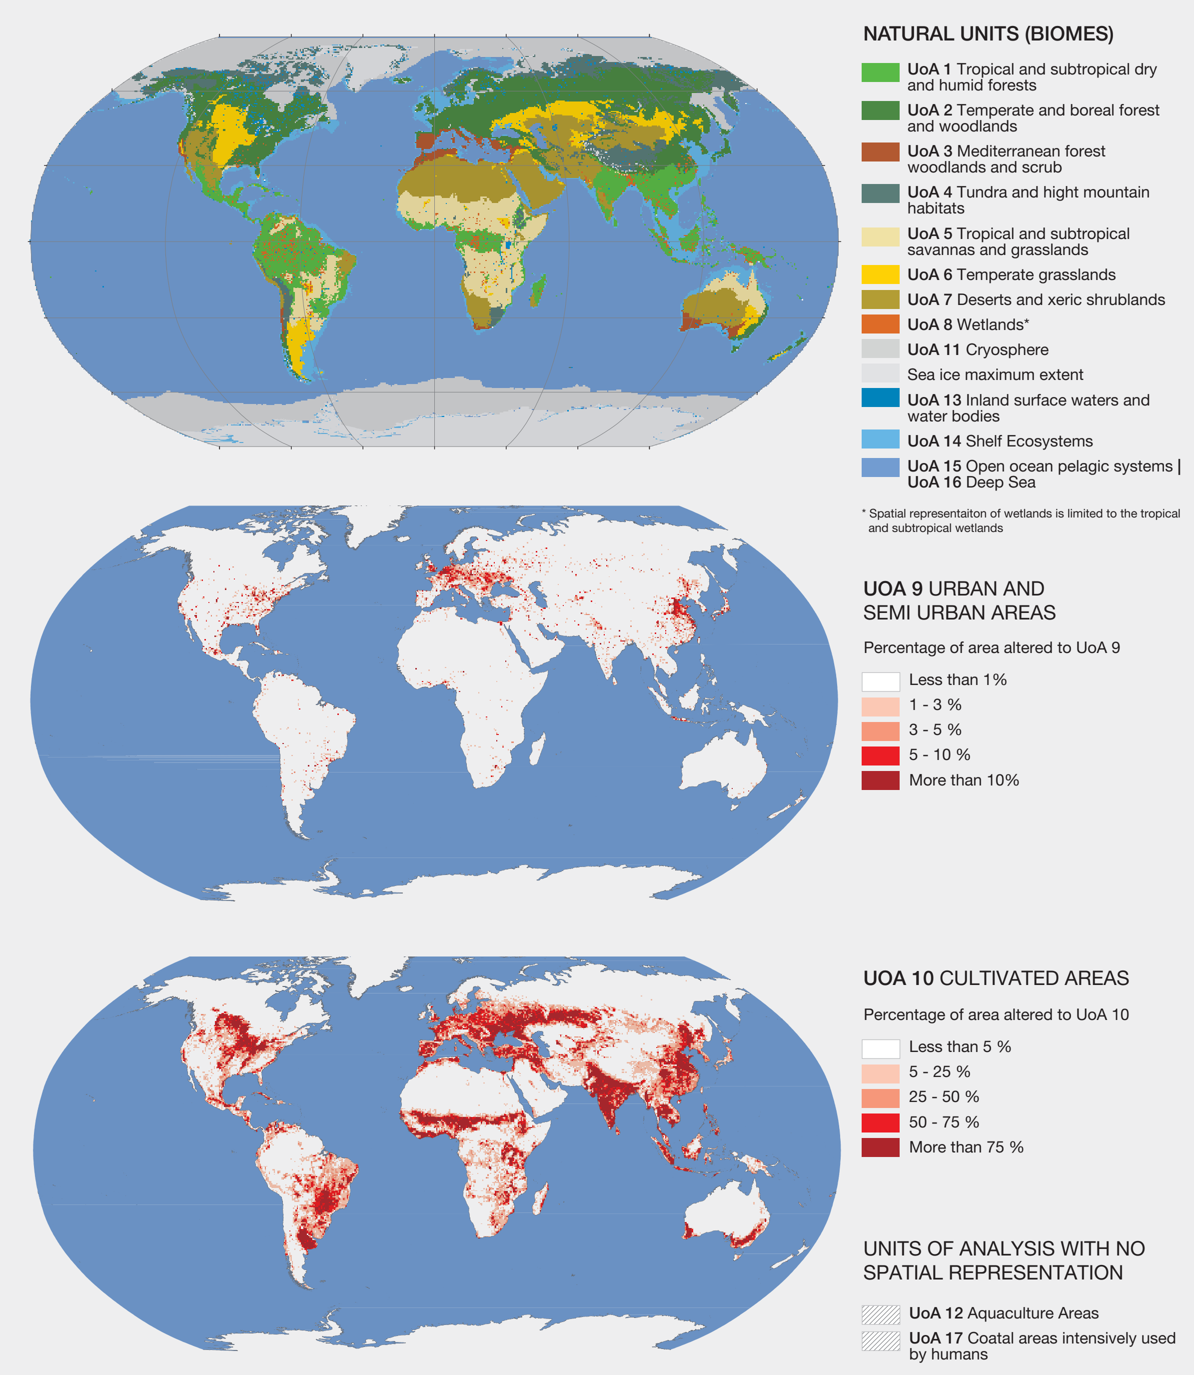

Figure 1 7 **Maps of the IPBES Units of Analysis; depicting both natural biomes and anthromes for the globe.**

The top map illustrates the biomes, followed by two maps of anthrome extent: urban and semi-urban areas (in the middle), and cultivated areas (in the bottom). Higher percentages of anthrome area are represented by deeper red tones. For more information on the description of IPBES Units of Analysis please see Supplementary Material 1.5.
Access the spatial data layers here: https://doi.org/10.5281/zenodo.3975694.

judgment can be deliberated (Turnhout, 2009; Turnhout *et al.*, 2007). Yet, as it has also been noted in the discussion of the NCP and values above, the selection of indicators reflects specific views and values.

Authors are aware of the limitations of indicators, both single or composite, to capture the complexities of the 'real world' or to represent different perspectives on a problem (i.e., proxy). Indicators are by nature restricted to what can be measured and for which there are available data at a given unit of analysis and resolution, ideally generated with the same methods, referring the same system boundaries, and being of comparable quality. These limitations are especially significant when it comes to nature's non-material contributions to people and aspects of a good quality of life, as well as to represent the perspectives of Indigenous Peoples and Local Communities. As no single indicator can provide information on all policy relevant aspects, assessments rely on selected sets of indicators that are available at, or that can be aggregated or scaled up to the global level. **Figure 1.8** shows a conceptual diagram illustrating connections among types of evidence as used in an assessment. The flow of data to information and knowledge relevant to an assessment involves both direct use and interpretation through different disciplinary and knowledge system lenses, such as how raw data on temporal or spatial variation in drivers and pressures on nature can be used independently or combined with other types of evidence to derive conclusions and inferences, such as those used for future projections.

The initial discussion of IPBES indicators began in 2015, aimed at providing common indicators for the IPBES

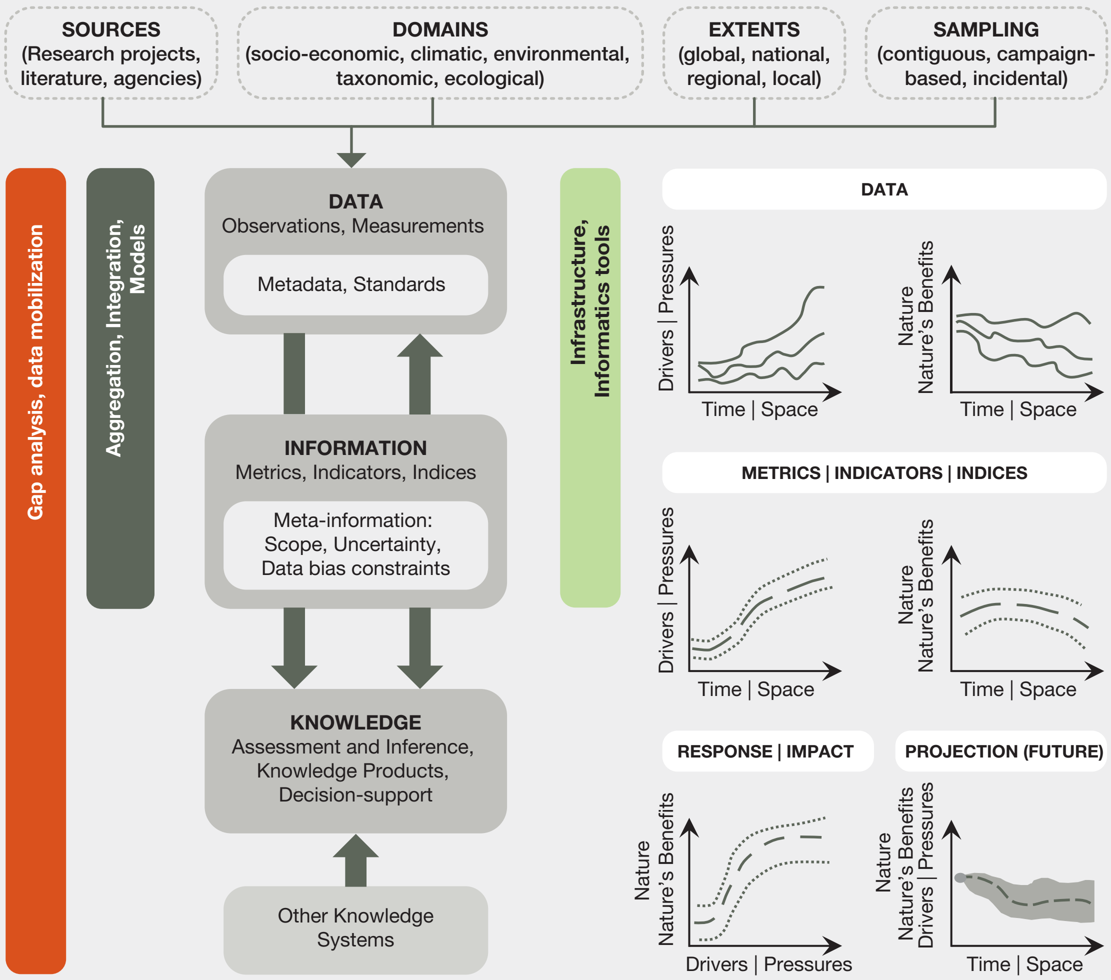

Figure 1 8 **Conceptual connection among types of evidence.**

The left side conveys the flow of data to information and knowledge relevant to IPBES, facilitated by a variety of approaches highlighted in colored boxes. Data may lead to knowledge directly or, outside this hierarchy of scientific inference, come from other knowledge systems. The right portion illustrates how raw data on temporal or spatial variation in drivers and nature (biodiversity and ecosystem properties and processes) may be combined to establish information about them, such as in the form of metrics, indicators or indices. Other knowledge systems directly contribute to assessment and inference for future projection. A combination of data or information from science and other sources contribute to knowledge about causal associations between drivers and impacts, which may then be used for projection. Source: Walter Jetz, Yale University.

For more information on the list of Core and Highlighted Indicators please see Supplementary Material 1.6 and 1.7.

Box 1 5 **IPBES principles for choosing indicators[6].**

1. **Policy relevant:** Indicators should provide policy-relevant information at a level appropriate for decision-making. Where possible, indicators should allow for assessment of changes in ecosystem status related to baselines and agreed policy targets.

2. **Scientifically sound:** Indicators should be based on clearly defined, verifiable, and scientifically acceptable data, collected using standard methods with known accuracy and precision or based on traditional knowledge that has been validated in an appropriate way.

3. **Simple and easy to understand:** Indicators should provide clear, unambiguous information that is easily understood. It is important to jointly involve policymakers, major stakeholders, and experts in selecting or developing indicators to ensure that the indicators are appropriate and widely accepted.

4. **Practical and affordable:** Obtaining or using data on the indicator should be practical and affordable.

5. **Sensitive to relevant changes:** Indicators should be sensitive and able to detect changes at time frames and spatial scales that are relevant to the decision-making. At the same time, they should be robust to measurement errors or random environmental variability in order to prevent "false alarms". The most useful indicators are those that can detect change before it is too late to correct the problems.

6. **Suitable for aggregation and disaggregation:** Indicators should be designed in a manner that facilitates aggregation or disaggregation at a range of spatial and temporal scales for different purposes. Indicators that can be aggregated for ecosystem as well as political boundaries are very useful.

regional assessments process; this originally involved regional assessment authors and experts of the IPBES Knowledge and Data Task Force, specifically, the task group on indicators. In addition to indicators related to Quality of Life **(Table 1.1)**, two main sets of biodiversity-related indicators were considered in the global assessment: 1) Core Indicators (n=30) and 2) Highlighted Indicators (n=42), which are presented and described in Supplementary Materials 1.6 and 1.7. Assessment authors used all available core and highlighted indicators in addition to other indicators or data sources they considered appropriate based on expert judgment (see **Box 1.5**).

Complementary sets of indicators were used when needed and available for analysing the Aichi Biodiversity Targets and the SDGs, which have their specific lists of indicators associated with different targets and goals. Chapters 2 and 3 also benefited from using indicators considered more relevant to Indigenous Peoples and Local Communities. In the case of Chapter 3 this was done through a systematic literature review for each Aichi Biodiversity Target and SDG analysed. Chapter 2 also considered indicators from and relevant to Indigenous Peoples and Local Communities as applied to different units of analysis.

Finally, at the level of experimentation, the global assessment piloted the concept of 'bundles of social-ecological indicators' (SES indicator bundles) with the theme of food security. Following a targeted workshop held around this theme, multiple bundles of indicators were identified tying together socio-ecological indicators with existing IPBES Core and Highlighted indicators. This category of social-ecological indicators emerged from the process of identifying Core and Highlighted Indicators as it became evident that there are large gaps in the existing indicator sets relevant to IPBES assessments in terms of evaluating the relationships embedded in the IPBES conceptual framework, including nature's contributions to people and good quality of life. Although these SES indicators and their bundles were used only experimentally, the piloting exercise provided useful guidelines for authors to examine issues of food security using as many and diverse indicators as possible.

1.3.6 Literature review

The scope of the IPBES global assessment is vast, examining past, present and possible future trends in multi-scale interactions between people and nature, taking into consideration different worldviews and knowledge systems. Within the science-policy interface the challenge is to approach, package and communicate the findings, which emerged from systematic evaluations of evidence in combination with input from transparent and open reviews, in a way that can be accessible and useful to decision makers.

The global assessment is based on existing data (including, as appropriate, national data), published scientific and grey literature and other information, including indigenous and local knowledge (see section 1.3.2.2), according to the guidelines of IPBES. Grey literature includes government publications, policy documents and briefs, online publications, technical reports and datasets etc. Based on the broad search strings and filters for output

9. Guide on the production and integration of assessments from and across all scales (deliverable 2 (a)); Modified from Ash et al. 2010 IPBES/4/INF/9 – IPBES Guide on the production and integration of assessments from and across all scales (deliverable 2 (a)).

results for systematic reviews in various databases/search engines, grey literature was not excluded from output results and held to the same criteria as all other literature and publications. The global assessment also considers IPBES' regional, thematic and methodological assessments and guidelines, as well as other relevant global assessments such as the Global Biodiversity Outlook series, the IUCN Red List of Threatened Species, assessments by the Food and Agriculture Organization of the United Nations, the Global Environmental Outlook series, the reports of the Intergovernmental Panel on Climate Change (IPCC), the Millennium Ecosystem Assessment, the first World Ocean Assessment (WOA I) and other assessments prepared under the Regular Process for Global Reporting and Assessment of the State of the Marine Environment, including socio-economic aspects.

How authors approach the assessment of the growing evidence base is a critical step in how the key findings are developed. Apart from this Chapter 1, all chapters used a combination of systematic and expert-based reviews to evaluate available evidence. A flexible protocol for systematic review was developed as a framework to guide authors, based on methods developed by the Collaboration for Environmental Evidence (2013)[10].

The suggested protocol within the global assessment aimed to achieve:

- **Transparency:** methods for identifying and selecting resources are reported;
- **Equivalent quality across chapters:** each chapter follows a similar approach;
- **Reduced bias:** resources known to authors are weighed against the best available resources; published and grey literature are searched concurrently;
- **Repeatability:** methods of identifying resources can be repeated or refined in subsequent assessments;
- **Efficient use of author time:** clear guidelines on how to search helps authors plan their work;
- **Efficient use of existing resources**: international efforts to compile environmental evidence for policy and practice are actively incorporated;
- **Balance** between the rigor of systematic review and the timeline and literature cut-off dates of an IPBES assessment.

The process involves two main sequential steps: 1) when applicable, concurrent database searches of different kinds of literature (e.g., peer reviewed and "grey" published literature, unpublished but openly available reports and databases) to minimize potential biases and 2) personal knowledge and experience of authors regarding key seminal resources or publications not appearing as an output from first step. The cut-off date for the inclusion of published sources was 30 April 2018. However, exceptions for including sources published after this date were made on the basis of reviewers' comments and the publication of relevant new evidence. In addition to systematic literature reviews carried out across chapters, an additional effort was made in chapter 3 to carry out systematic literature review to evaluate each Aichi Biodiversity Target and relevant SDG from the perspective of Indigenous Peoples and Local Communities. 32 Contributing Authors were involved and a total of 1760 literature references were compiled and analysed for this purpose (see chapter 3). In addition to this systematic review, the analysis of ILK/IPLC issues also benefited from an "Online Call for Collaboration"[11] (Table 1.4, Supplementary Material 1.4), which contributed around 1200 references, which were reviewed and selected to inform specific sections of the assessment.

In most cases, the method for literature review also included a priority order for inclusion of scientific evidence in the assessment: **Collated synopsis or summary > Systematic Review > Meta-analysis > Review >Individual Studies or case studies > compiled expert opinion.**

This order of priority assumes resources at each level are of equivalent quality and relevance. A combination of resources was discussed by authors to represent the most relevant and highest quality evidence. During chapter meetings, authors discussed the highest level of synthesis available as a priority and supplemented with levels below if necessary to fully cover and evaluate the subject/topic, or to include the most up to date information.

Across all chapters of the global assessment in the underlying chapter text, references are cited in-text with the full reference at the end of each chapter. Across all chapter executive summaries and the summary for policymakers' background text, traceability is indicated to chapter subsections enclosed in curly brackets. Each chapter includes a discussion of the literature review process in the main text or as part of the chapter's supplementary materials.

11. Launched 25 July 2017.

1.3.7 Confidence framework

A qualitative method of communicating the level of uncertainty and confidence in a key finding or statement using accessible and agreed upon terms and language has been essential to communicate assessment findings to decision-makers. The evaluation of confidence of assessment findings in the global assessment is based on the experience of previous IPBES assessments, which in turn benefited from other international and intergovernmental assessments, such as the Millennium Ecosystem Assessment, the Intergovernmental Panel on Climate Change (IPCC), and the UK National Ecosystem Assessment (UK-NEA).

The global assessment followed the schematics and criteria presented in **Figure 1.9** to guide authors in the process of assessing and communicating the degree of uncertainty, or confidence, related to key findings. This four-box confidence framework developed for IPBES assessments and its key findings are based on level of agreement of experts using their judgment (x-axis) in combination with the quantity and quality of evidence assessed (y-axis – **Figure 1.9**). The evidence includes publications, data, theory, models and information etc. Further details of the approach are documented in the note by the secretariat on the information on work related to the guide on the production of assessments (IPBES/6/INF/17).

The summary terms to describe the evidence are:

- ***Well established:*** comprehensive meta-analysis or other synthesis or multiple independent studies that agree.
- ***Established but incomplete*:** general agreement although only a limited number of studies exist; no comprehensive synthesis and/or the studies that exist address the question imprecisely.
- ***Unresolved*:** multiple independent studies exist but conclusions do not agree.
- ***Inconclusive*:** limited evidence, recognizing major knowledge gaps.

Following other IPBES assessments, the global assessment does not use a likelihood scale or probabilistic certainty scale.

The synthesis of this large volume of evidence is challenging and complex and relies strongly on authors' expertise and joint deliberations, including authors from multiple disciplinary backgrounds and knowledgeable of issues related to other knowledge systems, particularly Indigenous Peoples and Local Communities. These confidence terms inform and communicate to decision-makers what the assessment author teams have high confidence in as well as what requires further investigation to allow decision makers to make informed decisions.

Figure 1 9 **The four-box model for the qualitative communication of confidence.**

Confidence increases towards the top-right corner as suggested by the increasing strength of shading. Source: IPBES (2016).

CHAPTER **2.1**

STATUS AND TRENDS – DRIVERS OF CHANGE

EXECUTIVE SUMMARY

Global transformation involved key trade-offs, and inequalities, as growing interactions drove economic growth but also degradation.

Accelerations in consumption and interconnection have had trade-offs.

i. Meeting basic material needs, and rising hopes of growing populations has had trade-offs. Nature has been degraded by the aggregated impacts of myriad actions (*well established*). Today, humans extract more from the earth than ever before (~60 billion tons of renewable and nonrenewable resources) {2.1.2} with population doubling over 50 years {2.1.4} and the per person consumption of materials up 15% since 1980. Since 1970, global extraction of biomass, fossil fuels, minerals, and metals increased sixfold {2.1.6, 2.1.11, 2.1.14}. Urban area doubled since 1992 and half of agricultural expansion (1980–2000) was into tropical forests {2.1.13}. Fishing now covers over half the ocean {2.1.11}. Since 1980, greenhouse gas emissions doubled {2.1.11, 2.1.12}, raising average global temperature by at least 0.7 degrees {2.1.12} and plastic pollution increased tenfold {2.1.15}. Over 80% of global wastewater is discharged into the environment without treatment, while 300–400 million tons of heavy metals, solvents, toxic sludge, and other wastes are dumped into the world's waters each year {2.1.15}. Fertilizers enter coastal ecosystems, producing more than 400 hypoxic zones and affecting a total area of more than 245,000 km^2 {2.1.15}. The number of recorded invasive alien species doubled over 50 years {2.1.16}. Today, a full 75% of the terrestrial environment, 40% of the marine environment, and 50% of streams manifest severe impacts of degradation {2.1.12}.

ii. Accomplishments and shortfalls in the past – and the futures that we will shape – follow from variations in values, demography, innovation, trade and governance *(well established)*. Over the last 50 years, utilitarian instrumental views framed nature chiefly as a source of inputs, although narrow views have been challenged by varied institutions {2.1.3}. Irrespective of values, our increasing numbers drive degradation. Urban concentration shifts the trade-offs that we face {2.1.4}, while education affects changes in populations and per-person degradation – potentially at the cost of losses of the knowledge held by IPLCs {2.1.4}. Scarcities in nature's contributions have driven innovations that shift trade-offs, from the Green Revolution to massive hydroelectric dams, with genetic engineering, fracking, wind power, and other trends all to be fiercely debated {2.1.5}. The diffusion of such innovations could lower total degradation, while globalization has shifted degradation far away from consumption {2.1.5, 2.1.6}. Local community governance has organized more sustainable production {2.1.8} while nations, as 'global community citizens', have initiated a range of governance agreements, which had a range of fates. Nations also have adopted domestic conservation policies and even adjusted economic policies for nature {2.1.9, 2.1.10}. Supply chains are challenging national governance yet also signaling citizens' environmental preferences {2.1.7}.

iii. Within and across countries, outcomes trajectories have been unequal – for nature, for basic individual human needs, and for aggregate economic growth rates (*well established*). Forest cover stabilized in high income countries but since 1990 fell 30% in low income countries {2.1.11} as agricultural area fell in the former but rose in the latter {2.1.11, 2.1.13}. Natural assets values fell 1% in low income countries, since 1995, yet rose 5% in middle and upper-middle income countries {2.1.2, 2.1.13}. While 860 million people face food insecurity in Africa and Asia, obesity is rising in high and middle income countries {2.1.2}. Per capita demand for materials from nature is four times higher in high and low income countries {2.1.2}. Per capita consumption of animal protein rose by 50% during 1960–2010, to ~55 g/capita/day within the US and the EU, and ~30 g/capita/day in Latin America, but only ~15 g/capita/day in Asia and sub-Saharan Africa {2.1.2}. Contrasts are clear in the satisfaction of basic needs and the maintenance of nature and the two are linked, e.g., 40% of the globe's population lacks access to clean and safe drinking water and the highest gaps drive up child mortality in Africa {2.1.2}. Environments-based health burdens (e.g., air or water pollution) are born by people with lower-income {2.1.2, 2.1.15}, while GDP per capita is 34 times larger in developed than in developing countries and still it is rising faster within the former {2.1.2}.

I. Indirect Drivers: The root causes of transformations – both pros and cons

Values, demography, innovation, trade and governance drive outcomes

I-A. INDIRECT DRIVERS – VALUES

1 **The ways in which nature is conceived of and valued have had enormous implications for different consumption and production choices that influence degradation (*well established*).** Values differ across people, and evolve over time, informed by cultures and experiences {2.1.2.3}. Values toward nature may be grounded in ethical principles, and relationships, or predominantly utilitarian, focused on immediate preferences or leaning toward consideration of the future {2.1.2.3}. Globalization, migration, urbanization, and climate change are disruptors that can catalyse shifts in values towards nature {2.1.3}. Relational worldviews and values with strong ties to the land are central in many cultures around the world, associated to self-imposed restriction based on norms {2.1.3}. Narrower utilitarian, instrumental views of nature as a source of economic inputs, though, underpinned a variety of actions that promote resource extraction, industrialization, urbanization, and global trade, which continue to intensify {2.1.3}. Such views have been challenged in the last fifty years by calls for other ethics to mediate the interactions among and between humans and nature {2.1.3}. Examples of such narratives are the "living in harmony with nature" principle of the Rio 1992 Summit of The Earth conference, the Mother Earth emphasis within "the future we want" vision from Rio+20, and Pope Francis' recent encyclical {2.1.3}. Such visions of well-being and links to nature clearly have evolved over time {2.1.3}. For instance, if nature is degraded over time, while economies grow, core values may shift from a narrower orientation toward economic development to an integration of other dimensions such as varied capacities, justice, security and equity – all linking with nature in different ways {2.1.3}. Yet, stepping back, while all these views contributed to conservation and restoration in some locations, at the global level degradation of nature has continued despite increasing high-level awareness of degradation and scarcity {2.1.3}.

I-B. INDIRECT DRIVERS – DEMOGRAPHY

2 **For any values, population size is a big factor in scales of degradation (*well established*).** Human population has been growing, globally, doubling since 1970 overall, and despite regional variations this growth is expected to continue – with implications for degradation {2.1.4, 2.1.13}. The largest current increases are in least developed countries and in Africa, where the total population doubled, yet countries are starting to experience decreases, as developed countries have experienced in the past {2.1.4}. That said, those decreases in fertility rates result not from an automatic 'demographic transition', based upon economic development alone, but instead from conditions including women's empowerment and their access to family planning methods {2.1.3}.

3 **Education causes and is caused by economic growth – which in turn degrades, lowering human capital – yet education also can influence the rates of degradation *(well established)*.** Education has increased globally, in particular for women, with implications for human capital accumulation and, thereby, use of nature {2.1.4}. Together, those capital assets form a large share of national wealth, in particular for lower-income countries, and support an ongoing investment in education {2.1.4}. Environmental education can support lower degradation per unit of economic growth, through shifts in both production and individual habits {2.1.4}. This has benefits for human capital, as for example pollution lowers human productivity {2.1.4, 2.1.13}.

4 **Appreciation of indigenous and local knowledge (ILK) for managing nature is rising yet, at the same time, these local knowledge systems continue to be degraded (*well established*).** Indigenous and local knowledge (ILK) generated within IPLCs increasingly is seen as relevant for sustainable production. It offers broadly applicable alternatives to centralized and technically oriented solutions, which often have not substantially improved prospects for smaller producers {2.1.4, 2.1.5, 2.1.11, 2.1.13}. Yet, at the very same time, values and knowledge change with exposures including formal education, which can erode local worldviews that prioritized nature {2.1.3, 2.1.4}.

5 **Migration is both a cause and an effect of nature's degradation. Links in both directions are connected to patterns of vulnerability, in rural as well as urban areas (*well established*).** Migration has increased greatly, with 264 million international migrants entering other countries since 1970: more to developed countries {2.1.4}. Environmental and economic factors contribute to this migration. Today, environmental migrants number several million {2.1.2, 2.1.4} given inequity across regions in conditions for well-being and in provisioning and regulating contributions from nature that are among the most important determinants {2.1.2, 2.1.4}. Immigrants are often among the most vulnerable groups in society, with low access to nature's contributions to basic needs (water, sanitation and nutrition), yet they can have impacts on how nature is managed, including due to differences in values {2.1.2, 2.1.4}.

6 **Urbanization has been rapid, with enormous consequences including spatial patterns of land use**

that affect nature and NCP provision in urban and rural areas (*well established*). Today, close to 60% of the world's population lives in cities, with the fastest increases in Asia and the Pacific (25% rise in urban share in 1980–2010) and Africa (37%). There are 2.8 billion people now in megacities, with the fastest growth in low- (45% since 1980) and lower-middle income (39%) countries {2.1.4}. In the developing world, many of those people live in slums, with a low quality of environment and life {2.1.4}. Cities are sources of innovations in transport, industry and medicine, however, their high densities affect spatial patterns of land use and, thereby, nature {2.1.4}. Urban consumers have huge impacts and thus the potential to drive global changes {2.1.4}.

I-C. INDIRECT DRIVERS – TECHNOLOGY

7 **By region, IPLC practices are expanding in their use or disappearing (*well established*).** Much of the globe's population appropriates natural resources via rural or primary management of terrestrial, marine and freshwater ecosystems {2.1.2, 2.1.4, 2.1.5}. Related IPLCs practices based on long-standing knowledge of complex local ecological systems are seen to be resilient in IPLCs and among small-holders who together are ~2 billion people with 25% of land {2.1.5}. For instance, the agroforestry systems in many tropical countries have common characteristics: highly diversified, productive, complex, and using rotations in agriculture – as well as grazing, hunting, and fishing {2.1.5}. Yet a combination of lifestyle change, adaptation to climate change, seasonal migration, enclosures, privatization, and degradation of resources is strongly affecting both the settlement patterns and the lifestyles of the peoples who manage directly these diverse systems {2.1.5}.

8 **Technological advances in agriculture brought new benefits and costs (*well established*).** The Green Revolution brought opportunities and risks – exemplifying the need to consider both social and environmental trade-offs of innovations that benefit aggregate economic output {2.1.5}. Yields of rice, maize and wheat all increased, steadily, through greater application of irrigation, fertilizers, machinery, and seed varieties with higher yields and resistance to disease {2.1.5}. Yet despite aggregate gains, there were losses for some groups and for the environment (all raising possible trade-offs in agricultural genetic engineering) {2.1.5}. Food security may have fallen, for some, as production shifted from subsistence approaches which had fed Indigenous Peoples and Local Communities to monocultures that offered lower nutrition and access to markets {2.1.2, 2.1.5}. Further, despite greater food availability famine continued given institutional failures {2.1.2, 2.1.5}.

9 **Transitions from biomass to other energy sources have large impacts (*well established*).** Innovations have also greatly shifted how energy is produced and used around the world {2.1.5}. More than in other regions, households in sub-Saharan Africa and East Africa in particular still depend on biomass for domestic energy supply (and some high income countries are promoting renewable woody biomass). By setting, this can adversely affect human health and provision of contributions such as climate regulation and species habitats {2.1.5}. Information constraints, costs of capital, cultural preferences, and slow development of market institutions inhibit adoptions of modern fuels (e.g., liquid petroleum gas or electricity) {2.1.5}. The resulting deforestation not only lowers multiple contributions from nature but also threatens local supplies of energy {2.1.5, 2.1.12}. Demands for energy are also increasingly met by hydroelectric dams, with projected expansions in Latin America, Africa and Asia – again changing the production-degradation trade-offs {2.1.5}.

10 **Scarcity of nature's contributions has motivated various adjustments (*well established*).** Scarcities due to the degradation of nature have motivated shifts towards methods of production with lower material or environmental intensities {2.1.2.1}. For instance, households invest in cleaner stoves when rising incomes raise food consumption and thus also fuels consumption for cooking, such that indoor air quality falls {2.1.5}. Information on water quality motivates purification efforts from village infrastructures to household filters and bottled water {2.1.5}. In irrigation, scarcity of water quantity drives societal innovation like upstream-downstream allocation committees {2.1.5}. High prices for fossil fuels inspire novelties from rural extensions of electric grids to solar lamps and wind energy as well as batteries to store the output {2.1.5}. Positive effects of such innovations include those from their diffusion {2.1.5}. Broader use allows low income countries to avoid more environmentally destructive stages of economic growth by 'leapfrogging ahead' to more modern technologies of production with less degradation per unit of output {2.1.2.1}. Policy innovations may seek to spur such private innovation and adoption in light of critical degradations of nature {2.1.5}. Concerns about climate change, for instance, have led to proposals for carbon taxes, so that fuel and other prices reflect degradation and spur innovation in both mitigation and adaptation {2.1.5}.

I-D. INDIRECT DRIVERS – ECONOMY

11 **Transitions across sectors greatly influence the degradation of nature (*well established*).** As economies have grown, since 1950, many have shifted from agriculture toward both industry and services {2.1.6}, resulting in far higher shares in agriculture for value added, and employment, for the low income countries {2.1.6}. This affects management of nature, given that industrialized economies are characterized by the lowest materials intensities {2.1.6} – although we must keep in mind that this is due in part to their imports of agriculture (see below). At 0.5 tons of

domestic material consumption per US$1000 GDP, Europe and North America had the lowest 2013 intensities (down from 0.8 and 1 in 1980, respectively) {2.1.6}, as influenced by the methods noted above as well as sectors characterized by lower material per unit of economic output {2.1.6}. Yet even material efficiency can be swamped by rising production {2.1.6} and, while Asia's intensity remained relatively constant at ~2.5 tons per $1000 US GDP between 1980 and 1992, since 2003 intensity rose again, reaching 3.1 tons in 2013 – with immense impact on average global intensity {2.1.6}. African economies still have the highest intensities but gains over 3 0 years have been significant, e.g., from 4.2 tons per $1000 US GDP in 1980 to 3.3 tons in 2013 {2.1.6}. Evidence is mixed for time paths as economies grow, with the scale of consumption potentially offset by the mix of what is consumed and the way in which it is produced. Forests show reversals from degradation to recovery, while different pollution types have mixed paths, including due to trade {2.1.6, 2.1.13}.

12 Concentration of output and funds – sometimes associated with industrial innovation – influences what is produced and who benefits within and across countries (*well established*). Today, a few corporations and/or financiers often control large shares of the flows in any market, as well as amounts of capital assets that rival total revenues for a vast majority of countries {2.1.6}. These concentrations and their locations can hamper nature governance efforts (see below) {2.1.6}. Related, increasing shares of relevant sectors (e.g., coffee, fruits & vegetables, textiles & apparel, furniture) are supplied through value chains featuring considerable power at the retail ends {2.1.6}. This affects bargaining in exchanges of labor, and goods made with natural resources, including in the agricultural, fisheries and forestry sectors {2.1.6}. The location of power additionally affects regulatory oversight, with respect to environmental and social issues {2.1.6} – e.g., infrastructure development is known for its murky oversight and for its impacts upon nature. Funding via tax havens provided 68% of foreign capital for Amazonian soy and beef production and supported 70% of the vessels that are implicated in illegal, unreported and unregulated fishing {2.1.6, 2.1.11}.

13 Expanding trade means consumption affects degradation elsewhere (*well established*). Domestic material consumption per capita is highest for the developed countries and rapidly increasing for developing countries {2.1.2, 2.1.6}. Net goods flows vary, with some countries exporting more and others importing more {6}. Generally, developed countries reduced agricultural outputs over the last 50 years {2.1.6, 2.1.12}, and domestic water footprints, while importing crops from low income countries {2.1.6}. Environmental degradation from the production of those traded goods should be taken into account in assessing importing countries' net impacts, as total impacts can rise as domestic degradation falls {2.1.6}. This all influences equity too, e.g., whether in current market institutions suppliers of resources get 'equitable' compensation {2.1.6}. Different trade-offs arise when forest in low income countries is conserved by importing from high income countries, which can occur when efficient uses of capital lower the total areas in production – a phenomenon that may lower local incomes in that sector or spur other local sectors {2.1.6, 2.1.13}.

I-E. INDIRECT DRIVERS – GOVERNANCE

14 Pro-environmental signaling from consumers has grown, within multiple supply chains, yet the documentation of significant impacts on nature has been limited *(well established)*. Consumers at the ends of supply chains increasingly request information about the practices and the degradation linked with production. It can be facilitated by civil society, even across borders, as third parties collaborate with all of the private actors engaged in varied exchanges {2.1.6, 2.1.7}. Sustainable production certifications, terrestrial or marine, have risen greatly – for practices both environmental and social – yet despite some positive anecdotes, large impacts remain rare {2.1.6}.

15 Community governance has reduced or reversed degradation *(well established)*. Local actors have often conserved nature in common property systems – using local information, social norms, and abilities to impose cost {2.1.2, 2.1.8}. For centuries, IPLCs have contributed in this way to regional economies. In recent decades, the share of resources such as forests governed by Indigenous Peoples and Local Communities has grown {2.1.8}. Governance of shared resources can be facilitated by access to resources and information sharing; for instance, the unassessed smaller fisheries have fared worse {2.1.8}. Lacking comprehensive global data, we have sufficient cases of both successes and failures to have learned that community governance can be effective, yet it is not always {2.1.8}, and successes may rely in part on the roles of formal governments – e.g., without the public defense of local rights to manage resource and to exclude others, community areas of terrestrial and aquatic resources can be invaded and local efforts thus undermined {2.1.8}.

16 Public clarifications of rights influence investments that affect nature *(well established)*. Allocating private rights may generate conflicts concerning fairness or equity – yet clear rights can improve the efficiency of both investment and management by, e.g., smallholders who are incentivized to monitor nature locally, as for terrestrial multiple-use protected areas {2.1.8, 2.1.9}. Clear examples of the importance of rights also exist for large- and small-scale fisheries which used rights-based governance to maintain fish stocks {2.1.8}. Successes in management have been more frequent when such local rights were established in ways that respected local procedures. When government ignores local governance, public interventions can be destructive {2.1.8, 2.1.9}.

17 Public facilitation of sustainable land-use practices – such as agroforestry, agroecology – shows promise and perhaps potential for upscaling *(well established)*. With appropriate support, both financial and non-financial, sustainable agroecological practices have restored nature and its contributions. At varied scales, these have been observed in multiple locations across the globe from farmer-managed regeneration in dry parkland forests in Africa to a variety of Indigenous Peoples and Local Communities forests which function under forestry certifications {2.1.8}. Yet there can also be spillovers from such intervention – e.g., raising forest cover within a country may be facilitated by degradation elsewhere, as forest clearing simply shifts (see Asian examples) {2.1.8}.

18 Leading economic policies (e.g., roads, credit, private rights) can be adjusted to lower degradation of nature and potentially at a low cost to affected economies *(well established)*. One way governments stimulate economies is by investing in infrastructures for transport {2.1.9}. An obvious option to reduce its degradation is planning the routes for economic corridors {9}. With good local information, and processes, this can lower the costs of satisfying all stakeholder safeguards. Another core policy is establishing and enforcing clear tenure {2.1.8, 2.1.9}. Clarifying smallholder rights, including around customary tenure, can lower natural degradation {2.1.8, 2.1.9}. Further, it can spur greater investment in productivity, including within sustainable approaches.

19 Popular economic subsidies to degrading behaviours can be adjusted *(well established)*. Subsidies to various forms of energy (gasoline, electricity, etc.) are common and popular {2.1.9}. Possible adjustments include maintaining income transfers while removing price distortions that have raised environmentally damaging behaviours {2.1.9}. Alternatively, such credits, or transfers, can be made conditional on environmental metrics (just as in conservation policies below) {2.1.9}.

20 Public conservation policies like protected areas (PAs) and payments for ecosystem services (PES) reduce degradation if pressure was confronted and local actors engaged *(well established)*. A growing set 'payments for ecosystem services' (PES) compensate local actors for restrictions on uses of nature {2.1.9}. States also directly restrict production or extraction as in protected areas, the most extensive conservation measures, and undertaken costly actions to restore nature {2.1.9}. The gains for nature from such interventions have ranged from none to quite significant, based on whether and how pressures were confronted and if that included engaging with locals {2.1.9}. Impacts have been more common in high income countries, although funding transfers support interventions in low income countries that provide global public goods (e.g., carbon storage and habitats) {2.1.9}. Restrictions in low income countries can have positive local outcomes if support is provided yet unless local actors are a focus, economic costs can be higher than local benefits {2.1.9}. Generally, equity considerations can shift the choices and implementation of such policy. Policies' benefits and costs often are not equally distributed across either income levels or other dimensions, including race, though who bears the burden varies greatly with varied use patterns. Rights allocations and subsidies affect disparities, in either direction – again varying by context.

21 Governments have coordinated to reduce some types of degradation *(well established)*. National borders limit governance of transboundary resources. While various global 'commons' are judged to be worth conserving, including outside of national jurisdictions, accountability for failures of sustainable management there has been, at the least, uneven {2.1.10}. Like individuals in communities, nations can agree upon self-regulations that aid global 'commons' by mutually limiting degradation, even when facing high costs of organizing restrictions, as well as threats to their stability based on nations' political shifts over time {2.1.10}. For global coordination such as about biodiversity, the ozone layer, the climate system, the oceans, and poles, the coordination of actors can be even more difficult than for local communities {2.1.10}. Still, even if some policies have not had short-run impact, efforts are ongoing. For example, a relatively recent endorsement by 170 states of FAO's Code of Conduct for Responsible Fisheries (CCRF) in 1995, as well as a growing endorsement of The Agreement on Port State Measures to Prevent, Deter and Eliminate Illegal, Unreported and Unregulated Fishing, which came into force in June 2016 (now with 54 countries), have contributed to a lowering of illegal, unreported, and unregulated fishing {2.1.10}.

II. Direct Drivers

Demands have led to varied actions with multiple impacts upon nature

II-A. DIRECT DRIVERS – SECTORS (actions that link indirect drivers to aggregated impacts)

22 Fisheries have the largest footprint – with all of industrial extraction, aquaculture and mariculture, and the small fisheries critical for the livelihoods of millions *(well established)*. Today, industrial fishing has a footprint four times larger than agriculture, in which more than the 70,000 reported industrial fishing vessels cover at least 55% of the oceans – with hotspots for fishing in the northeast Atlantic, northwest Pacific, and upwelling regions off South America and West Africa {2.1.11}. Smaller fisheries account for over 90% of the commercial fishers (over 100 million people), as well as nearly half (46%) of the total global fish catch, yet the rest of global fish production is quite concentrated, within a few countries and a few corporations. Knowledge of inland fisheries is limited, despite their societal and ecological significance (accounting for up to 12% of global fisheries production). The contribution of aquaculture and mariculture to global fish production is increasing (6–9% growth in 1990–2012), with mixed effects upon coastal and marine ecosystems. While nearly 75% of the major marine fish stocks are currently depleted, or overexploited, since 1992 the global fishery community has incrementally adopted sustainable development principles created under the umbrella of mainstreaming biodiversity in fisheries.

23 **Agriculture, including grazing, has immense impacts upon terrestrial ecosystems, with important differences depending upon enterprise's intensity and size *(well established)*.** Agricultural systems remain quite varied, with plant- and animal-based systems, monocultures and mixed farming, plus newly emerging systems including organic, precision, and peri-urban approaches to production. Today, over a third of the world's land surface and ~3/4 of freshwater resources are devoted to agropastoral production {2.1.11}. Grazing occurs on ~50% of agricultural lands and ~70% of drylands {2.1.11}. About 25% of greenhouse gas (GHG) emissions come from land clearing, crop production, and fertilization, with animal-based food contributing 75% of it. Intensive agriculture has led to increases in food production at a cost of multiple regulating and non-tangible contributions from nature and even overall decreases in well-being in cases {2.1.11}. Small land holders (< 2 ha) contribute ~30% of global crop production and ~30% of the global food supply – using 24% of agricultural land and with the largest agrobiodiversity levels {2.1.11}. Their diverse agricultural systems, developed over centuries, have reduced negative impacts on nature, providing a wide range of material and regulating and non-material contributions, while generating the basis for sustainable agriculture intensification, soil management and integrated pest management {2.1.11}. Organic agriculture has developed rapidly, with variable outcomes: in general, it has contributed to higher biodiversity, improved soil or water quality, and nutritional values, although often at the expense of lowering yields and/or raising consumer prices {2.1.11}.

24 **Industrial roundwood harvests have risen, while bioenergy use rose dramatically in the rural areas of poorer regions, with some sustainable forest management (*well established*).** Reductions in forest cover during 1990 to 2015 totaled 290 million ha (~6%), although the areas of planted forests rose by 110 million ha (51%) {2.1.11}. Industrial roundwood made up half of the global harvest (3.9 billion m^3 in 2017), with fuelwood the other half {2.1.11}. Industrial harvest is falling in high income countries but rising in upper-middle and lower-middle income countries {2.1.11}. Global bioenergy uses almost tripled, largely in Africa, although bioenergy fell as a share – from 15% to 10% – with 30% of global fuelwood deemed unsustainable and over 200 million people facing rural fuelwood scarcities, mostly in South Asia and East Africa {2.1.11}. Sustainable forestry has been tried in many countries, over some time, including for forest certification, with some positive impacts upon forest cover and biodiversity, although mixed social impacts {2.1.11}.

25 **Harvesting wild plants and animals from land- and seascapes supports the livelihoods of a large share of the globe's population, raising sustainability concerns *(well established)*.** Over 350 million people – mostly lower-income households in Africa, Asia, Latin America – depend on non-timber forest products (NTFPs) for subsistence and income. Over six million tons of medium-to-large-sized mammals, birds, and reptiles are harvested in the tropics, annually, for bushmeat. Also, ~6 million wild ungulates are harvested in the Northern Hemisphere every year, by game hunters {2.1.11}. Evidence on sustainability is sparse, yet a well-managed harvesting of resources with strong local involvement could benefit both livelihoods and conservation {2.1.11}.

26 **Mining has risen dramatically, with big impacts on terrestrial biodiversity hotspots and global oceans, mostly in developing areas with weaker regulation *(established but incomplete)*.** Hundreds of mined products serve quite diverse purposes, globally, contributing more than 60% of 2014 GDP for 81 countries, with 17,000 large-scale sites in 171 countries. Most minerals are produced by large international corporations {2.1.11}. Still, small-scale mining is important in the livelihoods of many rural poor in the developing world – where many corporations have now located, given weaker environmental and social regulations (Africa is estimated to have 40% of global gold, 60% of cobalt, and 90% of platinum reserves) {2.1.9, 2.1.11}. Such impacts of mining are a growing concern, including per conflicts and illegality – although systematic quantitative data are unavailable {2.1.9, 2.1.11, 2.1.13}. Mining utilizes under 1% of global land but its negative impact on biodiversity, availability and quality of water, and human health may be larger than from agriculture {2.1.11}. Gold mining is of particular concern, given the rising demands and big impacts on biodiversity hotspots (despite protected areas) {2.1.11}. Ocean mining has been increasing, with ~6,500 offshore oil and gas installations, worldwide, in 53 countries (60% in the Gulf of Mexico) and possible expansion in the Artic and Antarctic regions as ice melts {2.1.11}.

27 Dams, roads, and cities have strong local negative impacts on nature, yet they also can have positive spillovers associated to increased efficiency and innovation (*well established*). While new infrastructure tends to have negative local consequences for nature, it can also have significant positive and negative spillovers {2.1.11}. The total number of dams has escalated in 50 years, with ~50,000 large dams (> 15 m height), and ~17 million reservoirs (> 0.01 ha) holding ~8,070 km^3 of water {2.1.11}. Urban area, while accounting less than 3% of the total land area, is rising faster than urban population and is associated with large effects beyond cities, which affect regional climates, hydrology and pollution {2.1.11}. Yet urban areas can excel in stewardship, e.g., raising flood resilience, reducing emissions, and constructing biodiversity friendly spaces {2.1.11}. New transport infrastructure tends to raise forest losses on frontiers, with direct negative impacts on biodiversity, plus exacerbate the environmental impacts of other developments, such as large mining operations {2.1.11}. Yet within more developed settings, shifts in transport costs can help forests {2.1.11}. Increasing human encroachment, land reclamation, and coastal development have strong impacts on coastal environments {2.1.11}. More and better planned infrastructure is found in higher income countries while fast, ill-planned expansion of infrastructure is found in rapidly growing urban and peri-urban settlements, especially in Africa and South and East Asia {2.1.11}.

28 Tourism has risen dramatically with huge impacts on nature overall, higher impacts for the higher-end options, and mixed outcomes from nature-based options (*well established*). Tourism grew dramatically in the last 20 years both domestically and internationally, especially from high and upper-middle income countries, with international travel levels tripling {2.1.11}. During 2009–2013, tourism's carbon footprint rose 40% to 4.5 Gt of carbon dioxide (8% of the total greenhouse gas emissions involved in transport and food consumption related to tourism) {2.1.11}. Most of those emissions are in, or from, high income countries. The impacts of a trip vary 1000-fold in terms of energy use, being higher for luxury accommodations and selected transportation types for the globally growing class of wealthy travelers {2.1.11}. The demand for nature-based or eco-tourism also has risen, with mixed effects on nature and societies {2.1.11}.

29 Both airborne and seaborne transportation of goods and people has risen dramatically, causing both increased pollution and a significant rise in invasive alien species (*well established*). Transport of goods and people has risen drastically over the last few decades, with the number of air flights doubling globally (1980–2010) and tripling for high income countries {2.1.11}. Seaborne carriage has doubled for oil, quadrupled for general cargo, and quintupled for grain and minerals over this period, while the voyage lengths have also increased {2.1.11}. The transport of goods and people have direct, indirect, and cumulative impacts upon nature including pollution (of air, water and soil), greenhouse gas emissions (contributing 15% of the global CO_2 emissions) and varied durable consequences along trade routes including introductions of invasive alien species {2.1.11}.

30 Restoration can offset current degradation levels, with varied intensities and outcomes, although global initiatives have focused mostly on our forests (*established but incomplete*). Restoration increasingly is required, given the ongoing degradation of various ecosystem types. It offers direct and indirect benefits through material, regulating and non-material NCP {2.1.11}. Approaches range from passive to active – with distinct costs, limitations, extents, and outcomes – though no global data are available on its current extent and outcomes {2.1.11}. One large-scale initiative is the Bonn Challenge aiming to restore 350 M ha of degraded forestland worldwide by 2030, yet no similar global challenges have been proposed for any non-forest ecosystems {2.1.11}.

31 Illegal extraction – including fishing, forestry and poaching – adds to unsustainability, yet is fostered by markets (local, global) and poor governance (*established but incomplete*). Illegal, unreported or unregulated (IUU) fishing made up 33% of the world's total catch in 2011, being highest off the coast of West Africa and in the Southwest Atlantic {2.1.11}. Illegal forestry supplies 10–15% of global timber, going up to 50% in some areas, worsening both revenues (for private or state owners) and livelihoods for poor rural inhabitants. Illegal pressures also increase the costs of trying sustainable forest management {2.1.11}. Illegal production of biofuels is large, especially for small, poor, informal actors in Africa {2.1.11}. Poaching is rising, pushing species (e.g., rhinos, tigers) toward extinction despite considerable international efforts {2.1.11}. Illegality is incentivized by high prices of species in demand and, for the low prices often received by the poor, driven by weak regulation and enforcement, with corruption and poor management {2.1.11}.

II-B. DIRECT DRIVERS – AGGREGATED IMPACTS OF ALL ACTIONS ON NATURE

32 The largest transformations in the last 30 years have been from increases in urban area, expansions of the areas fished, and the transformations of tropical forests (*well established*). Today, 75 per cent of the total land surface and 40 per cent of the ocean area are severely altered {2.1.12}. The total area of cities has doubled from 1992 to 2015, with the most severe impacts in tropical and subtropical savannas and grasslands {2.1.13}. Agriculture area in the tropics expanded mostly at the expense of tropical forests, with large expansions (~35 million ha) associated with cattle ranching in Latin America, linked to diets, and plantations, including for oil palm {2.1.13}. Land-cover changes have led to increasing fragmentation of the remaining forest as well {2.1.13}. Technological advance in agriculture, fisheries and aquaculture, and forestry has yielded at times irreversible shifts in ecosystems and in nature's contributions. These are exacerbated by greater livestock densities, changes in fire regimes, and intensifications leading to accelerated pollution of soils and water {2.1.13}. Soil degradation – including erosion, acidification, and salinity – has increased globally, although further systematic and reliable information will be required {2.1.13}.

33 **Demands for materials for nature have escalated, especially in developing countries and the Asia and the Pacific region, accounting for unprecedented global impacts *(well established)*.** The total demands for living and nonliving materials increased sixfold from 1970 to 2010, while the demand for materials used in construction and industry quadrupled during that time. The most drastic increases in demands for construction materials – on the order of ten times – occurred within developing countries and the Asia and the Pacific region. The extraction of living biomass from agriculture, forestry, fishing, hunting, and other activities has nearly tripled, globally – with the rapidly growing developing countries having the highest current levels for the rates of extraction for all living and nonliving materials {2.1.12, 2.1.14}.

34 **Pollution has been increasing at least as fast as total population, with key differences by region and by type of pollution – with more monitoring needed *(established but incomplete)*.** While quantitative assessment of pollution is limited in terms of the amount and quality of data in many countries, current data show pollution rising at least as fast as is the human population. Untreated urban sewage, industrial and agriculture run-offs, as well as oil spills, and dumping of toxic compounds, have had strong negative effects on freshwater and marine water quality {2.1.15}. Non-greenhouse gas atmospheric pollution, such particulate matter, is highest in countries with low or no regulation standards and poor enforcement, often at lower income. Fertilizer use rose fourfold in only 13 years, in Asia and the Pacific, and doubled in developing countries {2.1.11, 2.1.15}.

35 **Alien species increasingly are recorded across continents, although less in Africa, given variable rates of species 'invasibility' and monitoring capacity *(established but incomplete)*.** Current cumulative records of alien species are ~40 times larger in developed than in least developed countries. Though comparable across Europe and Central Asia, the Americas and Asia and the Pacific, they are ~4 times lower in Africa {2.1.12, 2.1.16}. This has resulted from increased trade and population densities but also large differences in detection capacities and 'invasibility' across alien species.

36 **Climate has changed since pre-industrial times due to anthropogenic activities and has influenced impacts, on nature and society, of many other critical drivers *(well established)*.** Anthropogenic activities – in particular those raising greenhouse gas emissions – are estimated to have caused approximately a 1.0°C warming by 2017, versus pre-industrial times, with ~0.2°C (±0.1°C) rises per decade. The fastest changes are observed in flat landscapes at higher latitudes {2.1.17}. The frequency and the magnitude of extreme weather events both have increased across the last five decades, while the global average sea level rose at a rate of over 3 mm yr^{-1} over the last decades {2.1.12, 2.1.17}. Greenhouse gas emissions per capita are highest for developed countries, though are decreasing there; they are followed by those in developing countries where they have increased by 10% since 1970. Decreases are associated to changes in behaviour, due to perceived threats, plus responses in governance and innovation – as well as some shifts in emissions to other countries {2.1.17}.

III. Development Pathways

Dominant development dynamics involved complex interactions across countries and regions, leading to inequalities in nature and trade-offs

37 **Rising interactions via global trade shifted consumption's footprints *(well established)*.** The consumption footprint per capita of each country, measured as the amount of land needed to support consumption, rises with per capita income or per capita GDP. Thus, it is far from equal. It rises even more rapidly for elements beyond the consuming country's borders that can reflect stronger governance of nature within the consuming countries. That affects nature more in low income countries with weaker governance {2.1.18}. Alternatively, production might shift to more efficient locations and reduce total degradation as efficient production lowers market incentives for supply. Strategies in international governance also affect nature beyond countries' borders. For instance, protected areas can block inefficient production in forest habitats in low income tropical countries that are highly prized, shifting production to less prized locations elsewhere. On net, though, trade-based degradation has flowed toward those countries with lower income.

38 **The trade-offs between economic growth and degradation have shifted *(well established)*.** Even for higher-income countries, earlier economic development during the last 50 years mostly occurred at the expense of local nature. When trade and governance increased imports

of nature from low income countries, economic aid (perhaps compensating global public goods as above) could provide those countries with local net benefits {2.1.2, 2.1.18}. In contrast, concentrating power in global supply chains lowers economic returns in lower-income countries from appropriations of nature – sometimes with net local environmental and economic costs. These interactions helped high income countries to protect their nature while continuing to have economic growth {2.1.2, 2.1.18}, although the relative rates of growth, based on such exchanges, depend on the bargaining power.

39 **Economic and environmental inequality evolved, across income levels (*well established*)**. Globally, GDP per capita has increased relatively steadily over time {2.1.2}. Increases have been unequal over space, however. Globally, economic inequalities have steadily increased (note that within countries, the evolutions of inequalities have been uneven, averaging out to little change). That in turn can shift bargaining power, yielding unequal divisions of the gains from interactions, though dynamics can include convergence, with more rapid GDP growth in emerging economies (more generally, developing countries are intermediate between the developed and least developed countries' pathways). Inequalities within and among countries can make collective actions (coordination, cooperation) that are needed for conserving and restoring nature's contributions even harder to achieve {2.1.2, 2.1.18}.

40 **Social instabilities linked to scarcities in nature are part of current and future threats to nature based upon economic, social, and geopolitical conflicts (*established but incomplete*)**. Conflicts result from interactions concerning availability and control over nature's contributions {2.1.18}. More than 2,500 conflicts over fossil fuels, water, food and land are currently occurring. Lower-income countries that tend to be rich in natural resources have experienced more conflict – exacerbating environmental degradation, lowering GDP growth, and raising migration {2.1.18}. Communities expelled from lands or threatened by degradation (e.g., deforestation, mining or the expansion of industrial logging) have been associated with related violence (e.g., ~1,000 activists and journalists killed during 2002 to 2013) {2.1.11, 2.1.18}. Armed conflicts have direct physical impacts on ecosystems, beyond their destabilizing effects on resource uses and productivity {2.1.18}. The ecosystems relatively untouched by human activities can be particularly vulnerable to intrusions of this type, because remote ecosystems with few humans have harbored illegal activities {2.1.11, 2.1.18}.

41 **Social-ecological dynamics yield balances and regime shifts (*established but incomplete*)**. Interactions among drivers can generate iterative dynamics that raise outcomes variability {2.1.18}. Some systems equilibrate, e.g., if scarcities are perceived then prices and governance initiatives may rise as responses, then recede {2.1.18}. Other systemic interactions have led to rapid changes and extreme outcomes including 'regime shifts' for ecosystem functions: marine hypoxic zones; species invasions; or desertification {2.1.18}. Some collapses have arisen in high income settings, as challenges for rulemaking and enforcement confounded local regulations, despite capacities. Some dysfunctions have resulted in conflicts, in and across societies, which extend dysfunction: e.g., food shortages due to climate shifts, and unequal access, have generated 'food riots' {2.1.18}. Serious conflicts and societal shifts have arisen within mining, water, biodiversity, and land – sometimes financed by resource extraction and exacerbating environmental degradation {2.1.18}.

42 **Dynamics include (nonlinear) recoveries to good balances (*established but incomplete*)**. Systemic interactions have led some settings towards a positive 'equilibrium', with a reduction of degradation or a restoration of nature {2.1.18}. For example: policies that affect a fishery stock by shifting some behaviours may 'tip' the setting into sustainable harvesting, in which individual actors shift into making choices consistent with stock preservation; or, conservation sometimes spreads if one group observes benefits to earlier adopters and, so, chooses to mimic their actions. Further, individual nations' participation in some global collective agreements has spread when payoffs from joining rise with the participation of other countries – so leadership matters {2.1.18}.

2.1.1 INTRODUCTION

The globe's diverse citizens strive to achieve a good quality of life, with diverse perspectives on what is needed to achieve that, as a result of varied relationships with each other and with nature. Nature supports all these individual and collective pursuits, through contributions detailed in this volume (see chapter 2.3): provisioning or material contributions, such as food and timber; regulating contributions, such as climate regulation and protection of soils; and cultural and non-material contributions, such as learning and inspiration. Meeting the individual and societal demands for nature has posed severe and heterogeneous challenges. Some groups still do not have their basic needs met from nature's contributions yet increasing demands upon nature are exceeding rates at which contributions can be sustained (IPBES, 2018b, 2018e, 2018c, 2018d). At current trends, we risk drastic degradation, with drops in contributions critical for societies and uneven distributions of losses.

Basic needs and luxuries depend on nature, i.e., on land, plants and animals, minerals, and water whose supplies depend upon myriad functions of ecosystems, such as nutrient cycling and water purification. How nature is manipulated, including within markets, depends upon socioeconomic factors: values, incomes, technologies and power (i.e., who determines which development ideas are implemented and how). Scarcities drive human responses, including governance institutions, from norms to national policies. Yet markets' prices often fail to reflect scarcities in nature, thus degradation remains invisible in local and global economic systems, for rural and urban settings. Likewise, individuals and society often fail to fully recognize and to incorporate the value from nature's contributions, despite their immense importance for multiple dimensions of well-being.

For this global assessment of nature, and its contributions to people, we are concerned with all of these pursuits. Every one of the Sustainable Development Goals (SDGs), for instance, is critical. Yet we focus on the consequences for nature from economic and social development trajectories, over the past 50 years, that centrally involve interactions across local, national and global scales. Those consequences, in turn, enable or constrain potential for future development, sustainable or otherwise. Our focus in this chapter is on understanding the indirect and direct drivers affecting past and present, and influencing possible trajectories for nature, and people, at different scales.

To broadly describe the interactions between society and nature that underpin trajectories within development, we analyze the evolution of different categories of drivers that affect nature and its contributions to people. First, we cover **indirect drivers**, i.e., factors behind human choices that affect nature. This starts with values, as goals affect choices. We next consider 'demographic' (population, migration, education) and then 'technological' (innovation) factors. Next come the 'economic' factors: structural transition, i.e., shifts across economic sectors such as agriculture, manufacturing, and services; concentrated production, i.e., shifts in output shares for big actors; and trade as well as financial flows that continue to increase within and across national borders.

Finally, we consider 'governance', an overarching sub-category of **indirect drivers** that includes all types of governance. They respond to scarcities in nature's capacity to generate contributions: scarcities increase the likelihoods of responses although many other factors also determine them.

Within governance, we distinguish different forms, while emphasizing their many interactions. We start with efforts by private actors within supply chains, e.g., the certification of production processes for environmentally beneficial features for which at least some consumers would pay. Moving outside markets, we consider coordination at local levels within community governance. We then consider the governance by formal states, i.e. policies from local scale to national scale, and their interaction with community governance which can either enhance or worsen outcomes. Finally, we consider coordination across governments – i.e., 'global community governance' – that must address challenges similar to those which face smaller-scale community governance.

We then move to the **direct drivers**, i.e., direct human influences upon nature – in seven sections. The first section (2.1.11) covers human actions, e.g., farming, fishing, logging, and mining, that respond to indirect drivers and directly affect nature. Interventions often aim to shift such actions, based on theory and evidence about dominant dynamics. Section 2.1.12 gives an overview of all the influences on nature from those actions for aggregate influences upon nature, which are detailed in the following sections These include land/seascape change (2.1.13), resource extraction (2.1.14), pollution (2.1.15), invasive alien species (2.1.16) and climate change (2.1.17). Both sections consider efforts to reduce degradation and recover nature, i.e., restoration efforts and outcomes.

Following chapter 1, our final section (2.1.18) "closes the loop". Direct drivers feed processes in nature that, in turn, feed into the process of co-production of all nature's contributions to people (NCP). In turn, NCP abundance and scarcities affect the quality of life of everyone within a society and, thereby, spur shifts in indirect drivers such as values, market prices and other institutions. Thus, we can work through cases of drivers' consequences coming around to shape drivers' evolutions. We consider the implications of such iterations for future (perhaps sustainable) development pathways.

Understanding development trajectories with global interconnections.

Intensified global interconnections have been a defining feature of the last 50 years. Any global perspective includes how regional, national, and subnational trajectories – for nature, economic development and governance – have interacted at a global level. Figures below articulate how as a consequence, the trajectories observed across the last 50 years, while related to each other, have differed considerably across space and time, e.g., as experienced by different groups of countries in terms of nature **(Figure 2.1.1)**, economic growth, and environmental governance **(Figures 2.1.2-2.1.3)**. The figures aim to illustrate how least developed, developing, and developed countries followed distinct but interconnected trajectories, given differing and interacting bundles of indirect and direct drivers in and across regions with cumulative and/or cascading effects over time. In many cases, varied trajectories are present in single countries. An example for forests, in **Box 2.1.1**, illustrates how various interconnections of multiple drivers across and within regions shaped forest landscapes.

Observed historical trajectories for important elements of nature can be summarized using a few possible steps: degradation to start, almost surely; then possibly also stabilization, and recovery **(Figure 2.1.1)**. The trajectories for different societies are not necessarily independent, however, and we explore how they could be the result of interacting trajectories of indirect and direct drivers – due to individuals' and societal choices. For instance, if one society recovered certain capacities of nature after degrading them (as is observed in various regions especially in the 'Global North'), how could that transition have occurred within a world in which other societies did not choose or were not able to reverse related negative trends within nature? Looking across 50 years, were the observed transitions simply independent choices by heterogeneous societies to regulate more, or invest more in sustainability, or consume less? Or did recoveries rely upon degradation in other countries? And, going forward, what are the implications of those interactions for trajectories?

Next, we wish to consider whether multiple dynamics could generate each trajectory in **Figure 2.1.1** because exactly how a country or region managed to stabilize or to improve elements of nature affects not only the sustainability of those changes but also the implied consequences for others. For instance, some societies enjoyed greater initial endowments of particular natural resources – such as minerals, land, climate, and ecosystem productivity on many dimensions (Scheffer *et al.*, 2017) – which in general could improve those trajectories.

However, natural wealth alone has proven not to be sufficient for ongoing positive trajectories, independent of society's institutions and choices. In fact, many distinct evolutions of different bundles of indirect drivers could affect nature similarly – i.e., generate the same trajectories in **Figure 2.1.1** – yet differ greatly in trade, governance,

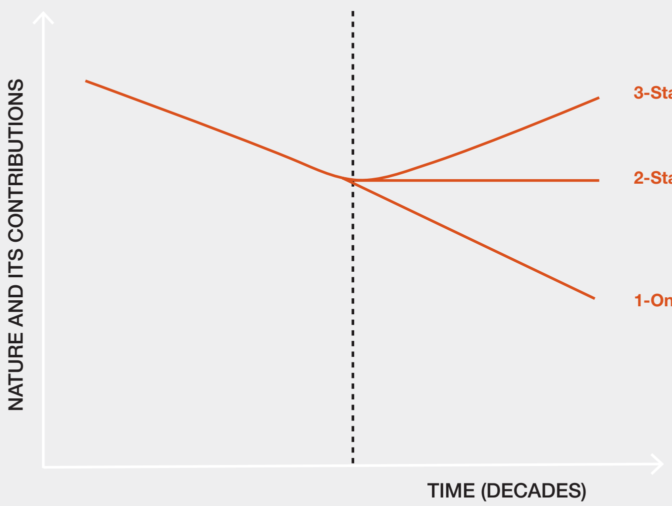

Figure 2 1 1 **Illustrative trajectories along differing development pathways for 'nature', i.e., its productive stocks or its capacity to generate valued contributions, at the time scale of decades.**

The first trajectory is ongoing degradation, the second is stabilization after degradation, and the third is not only stabilization but also a reversal or recovery. The vertical line is a point of transition, whose timing depends upon many factors, including scarcities in nature.

Box 2 1 1 Multiple dynamics driving forest cover can underlie stabilization or recovery.

Forests provide examples for such dynamics (IPBES, 2018a). Global forest cover has been close to stable in recent years, yet forest cover decreased in some regions while stabilizing or even recovering in others. Existing theories about processes underlying such trajectories (Meyfroidt *et al.*, 2018) propose dynamics that have similar forest trajectories but differ on other dimensions in **Figure 2.1.2**. Forest degradation often results from agricultural expansion, for which there are many examples, including within the tropics, where that remains a significant phenomenon (Barlow *et al.*, 2018; Curtis *et al.*, 2018; Hansen *et al.*, 2013). This is common enough that it could explain initial and continuing downward slopes within a version of **Figure 2.1.1** for forest.

'Forest transitions' (**Figure 2.1.1**, Trajectory #2/#3) were observed in Western Europe and North America (Mather & Needle, 1998; Rudel, 1998), then East and South Asia (Foster & Rosenzweig, 2003; Kauppi *et al.*, 2006), and parts of Latin America. Different dynamics underlying transitions have been highlighted in varied literatures (Caldas *et al.*, 2007; Geist *et al.*, 2006; Gutman *et al.*, 2004; Rindfuss *et al.*, 2004). We consider some below.

Intensification. For a fixed area, outputs can rise via changing knowledge and practices, inputs and tools to promote 'intensification' – such as double cropping or higher-yield crop varieties (Thaler, 2017). Incorporating trees is an agropastoral option which also aids biodiversity (Pagiola *et al.*, 2016; Perfecto & Vandermeer, 2010). If adoption of any of the above alternatives were to be universal, then forests might stabilize or even recover in all countries, while across-country inequality would depend upon biophysical and societal constraints on yield.

Transition to manufacturing/services. A distinct dynamic is sectoral transition from agriculture to manufacturing and services, within processes of both urban and industrial growth – often along with rural depopulation and a spatial contraction of increasingly intensive agricultural production. This may raise affluence and the demand for improving ecosystem health and ensuing regulating and cultural contributions (e.g., Mather & Needle, 1998; Rudel, 1998) that affect both governance and trade (see, e.g., Mather, 2007; Rudel *et al.*, 2005; Viña *et al.*, 2016).

Substitution by imports. Countries also have stabilized forest cover by importing wood or food, grown at the expense of forests elsewhere (Meyfroidt *et al.*, 2010). In this dynamic, recoveries rely on others' degradation. Some countries follow Trajectory #1, as still occurs in the tropics. With increasing global trade, sources of inequalities between countries include differences in who gained from these trades, given differences in power across firms and countries, including in abilities to increase value in forest and agricultural products through transformation processes.

economic outputs, and various inequalities. Further, within many of those dynamics, outcomes differ as a function of countries' development level (those additional dimensions plus broad differences across development levels motivate **Figure 2.1.2**).

Box 2.1.1 lists varied interconnections that shaped forest landscapes, both illustrating **Figure 2.1.1**'s trajectories, and their interconnections at the global level, and illustrating that there is a suite of different implications of the achievement of **Figure 2.1.1**'s trajectories. In and beyond forest cover, these differing and interrelated possible trajectories for nature involve some countries being able to 'transition' from the degradation of nature to a stabilization or a recovery within their borders, while others incur the costs of degradation. In other settings, the stabilization or the recovery of nature in one country is not dependent on degradation elsewhere, so reversal is possible for all.

Again, then, for forest cover, and beyond, the trajectories of countries can be highly contrasting (motivating **Figure 2.1.2**). In general, provisioning contributions from nature raised gross domestic product (GDP), even in per capita terms despite rising populations, during initial degradation of nature via transformations of ecosystems for agriculture (i.e., to the left of **Figure 2.1.2**'s transition). Further, between-country economic inequality rose – while falling or rising in different countries – since scales of economic activity differed. Output per unit of natural degradation also differed, as countries with higher income could combine more physical, financial, educational and social capital with their natural capital in production. They also could have had different past histories, e.g., longer periods of depending on nature beyond their borders, through colonization or trade. Thus, many countries' periods of early economic development had similar impacts on nature but differed in economic trajectories, including in trade and in (relatively rare) governance of nature.

Nonetheless, each trajectory involves particular trade-offs in meeting the society's diverse needs, through both production and conservation. Yet, since countries' trajectories are not independent, given rising global interconnections, which mechanisms or settings facilitate or drive transitions has significant implications for who reaps gains or bears the costs of degradation and recoveries. Some possible inequalities in trade-offs between gains and losses in nature and economic output, looking both within and across countries, are illustrated by contrasting trajectories in **Figure 2.1.3**.

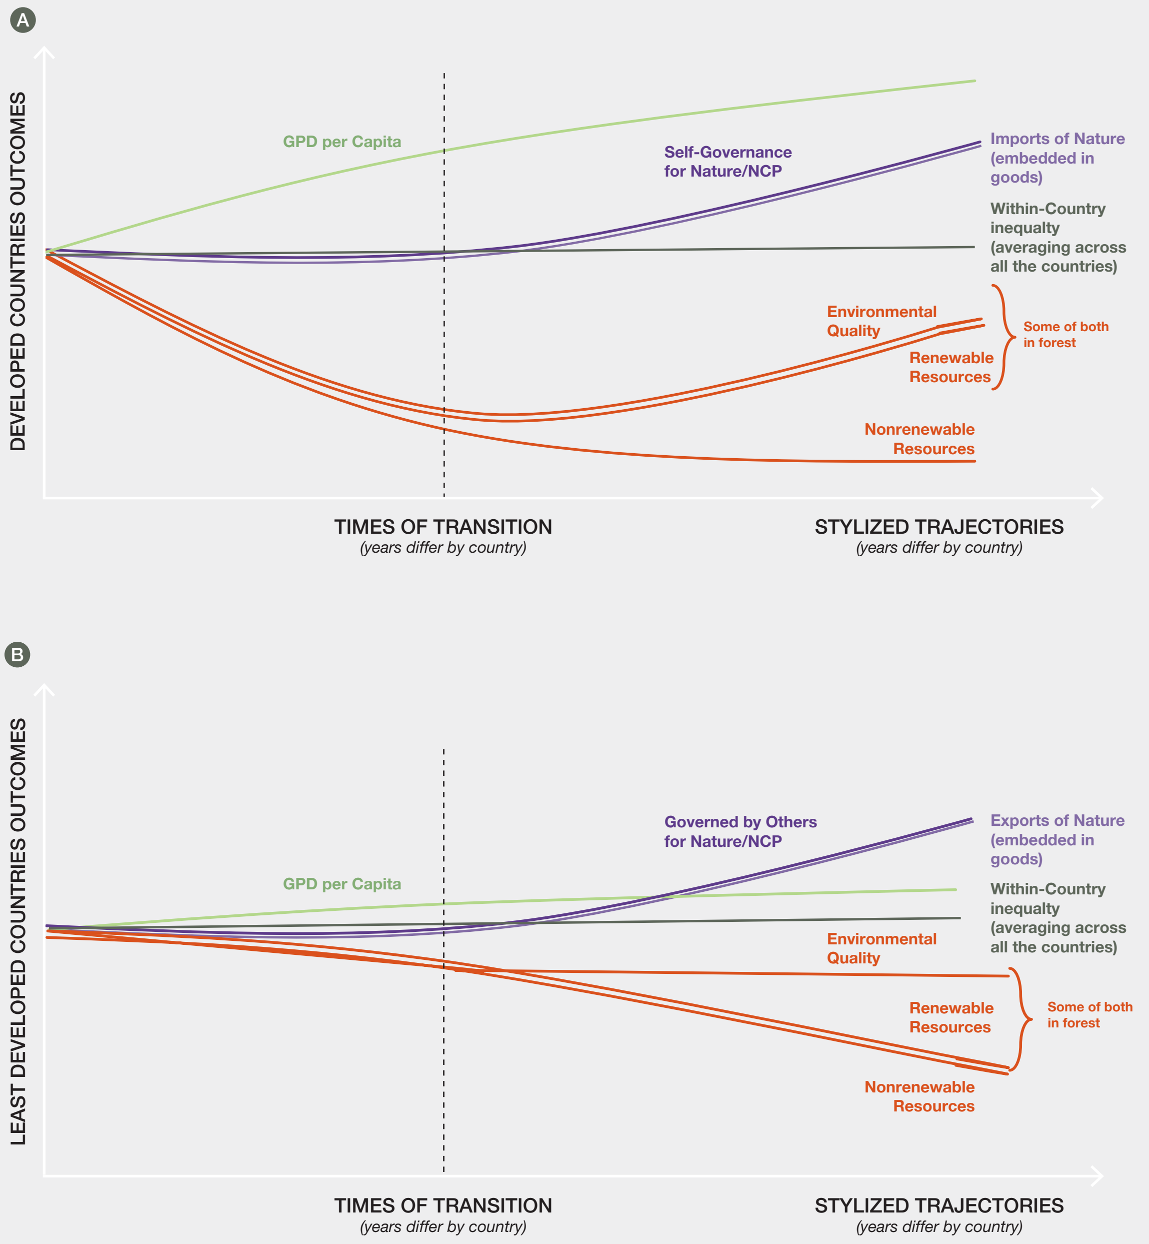

Figure 2 1 2 **Stylized sketches of average trajectories in developed countries outcomes A and least developed countries outcomes B.**

From bottom to top: quality of environment and natural resources ('renewable' like fish or trees, which regrow, or 'non-renewable' like oil or ores); institutional features of economies (i.e., trade) and societies (i.e., governance); gross domestic product (GDP) per capita; and inequality in GDP per capita. This figure builds upon **Figure 2.1.1**, with vertical lines indicating times for transitions that, in reality, happen at different times in different countries.

Consider, for instance, the degradation of nature as well as the other outcomes from expansion and intensification dynamics of economic activities. Regulations can limit the areas affected by those activities (e.g., agriculture), and a country also can invest to raise its outputs per unit area and, further, even to lower total 'environmental footprint' (e.g., abandon activities and reforest); which can produce the Self-Governing trajectory: recovery for nature, slower GDP growth **(Figure 2.1.3)**. Whether all this occurs depends on whether the society places a sufficiently high value on forest.

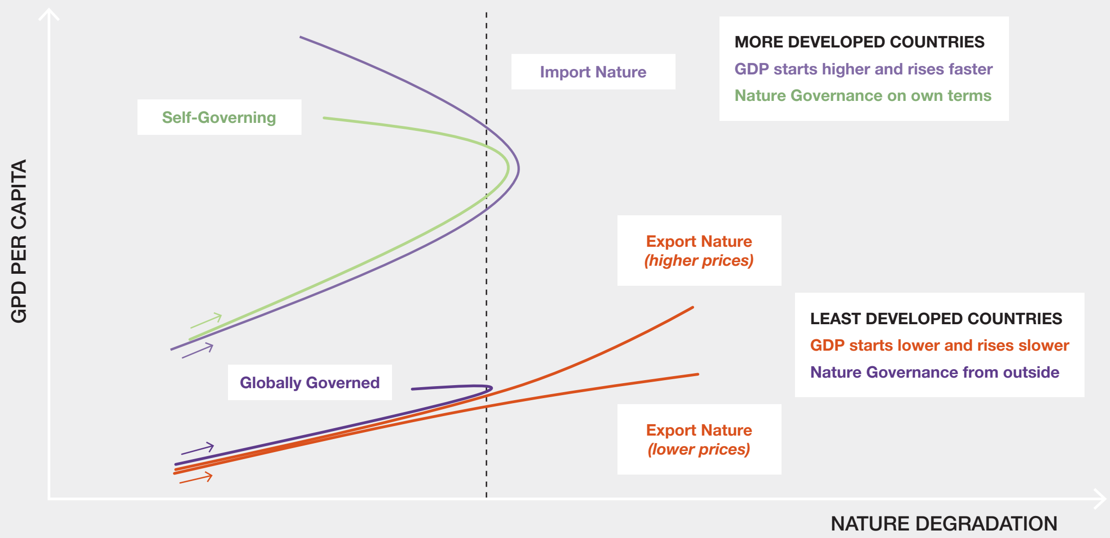

Figure 2 1 3 **Stylized sketches of cross-country interactions in trajectories for material contributions of nature.**

y-axis = GDP per capita and capacity for future material, regulating and non-material contributions, x-axis = nature. Imports and exports of nature are embodied in goods, e.g., water in food or trees in timber decrease for exporters and increase for importers. As in Figures 2.1.1 and 2.1.2, a vertical line indicates a point of possible societal transitions.

Instead, developed countries may conserve nature (e.g., forest cover) by importing forest and agricultural goods from least developed countries, albeit at the expense of nature for the exporters. For importers, an 'Import Nature' trajectory may be better than meeting needs by self-governing, though whether this occurs depends on whether exporters put a sufficiently low value on forests. The trade-offs depend on export prices, as illustrated in two Export Nature trajectories **(Figure 2.1.3)**.

Alternatively, developed countries may advocate – and cover the costs of – nature governance in least developed countries such as strict protected areas that make some local uses of forest illegal. That may provide global public goods – yet sometimes by imposing net costs on the local actors. A rise in nature could raise welfare for developed countries, yet lower GDP for least developed countries, if the latter cannot shift into other activities that support economies (Globally Governed trajectory). This motivates a quest for actions to help nature and local economies. For instance, forests might also increase if enforced protected areas flanked new railway links that facilitated urban growth.

2.1.2 PAST TRAJECTORIES, THEIR TRADE-OFFS AND INEQUALITIES

2.1.2.1 Maintain nature or meet society's many and diverse short-run goals?

Compared with pre-1980 realities, the world has changed rapidly **(Figure 2.1.4)**. Population, urban areas and international migration have risen greatly. Overall, quality of life has improved, in the senses of, e.g., lower child mortality, or higher caloric intake, and varied summaries such as the Human Development Index. Economic development generally has advanced, in terms of per capita GDP and per capita consumption, while the value of merchandise being exported has also increased. Yet, these improvements have come at a real cost: increasing impact upon nature. Since 1980, food production systems have intensified and, although the overall areas covered by cities and agriculture have not drastically increased, more fertilizer and pesticides are being used while total pollution (including greenhouse gas emissions), the number of invasive alien species, and temperature anomalies are increasing, and biodiversity intactness is decreasing (see chapter 2.2 for more on this variable) – despite increasing efforts to protect key

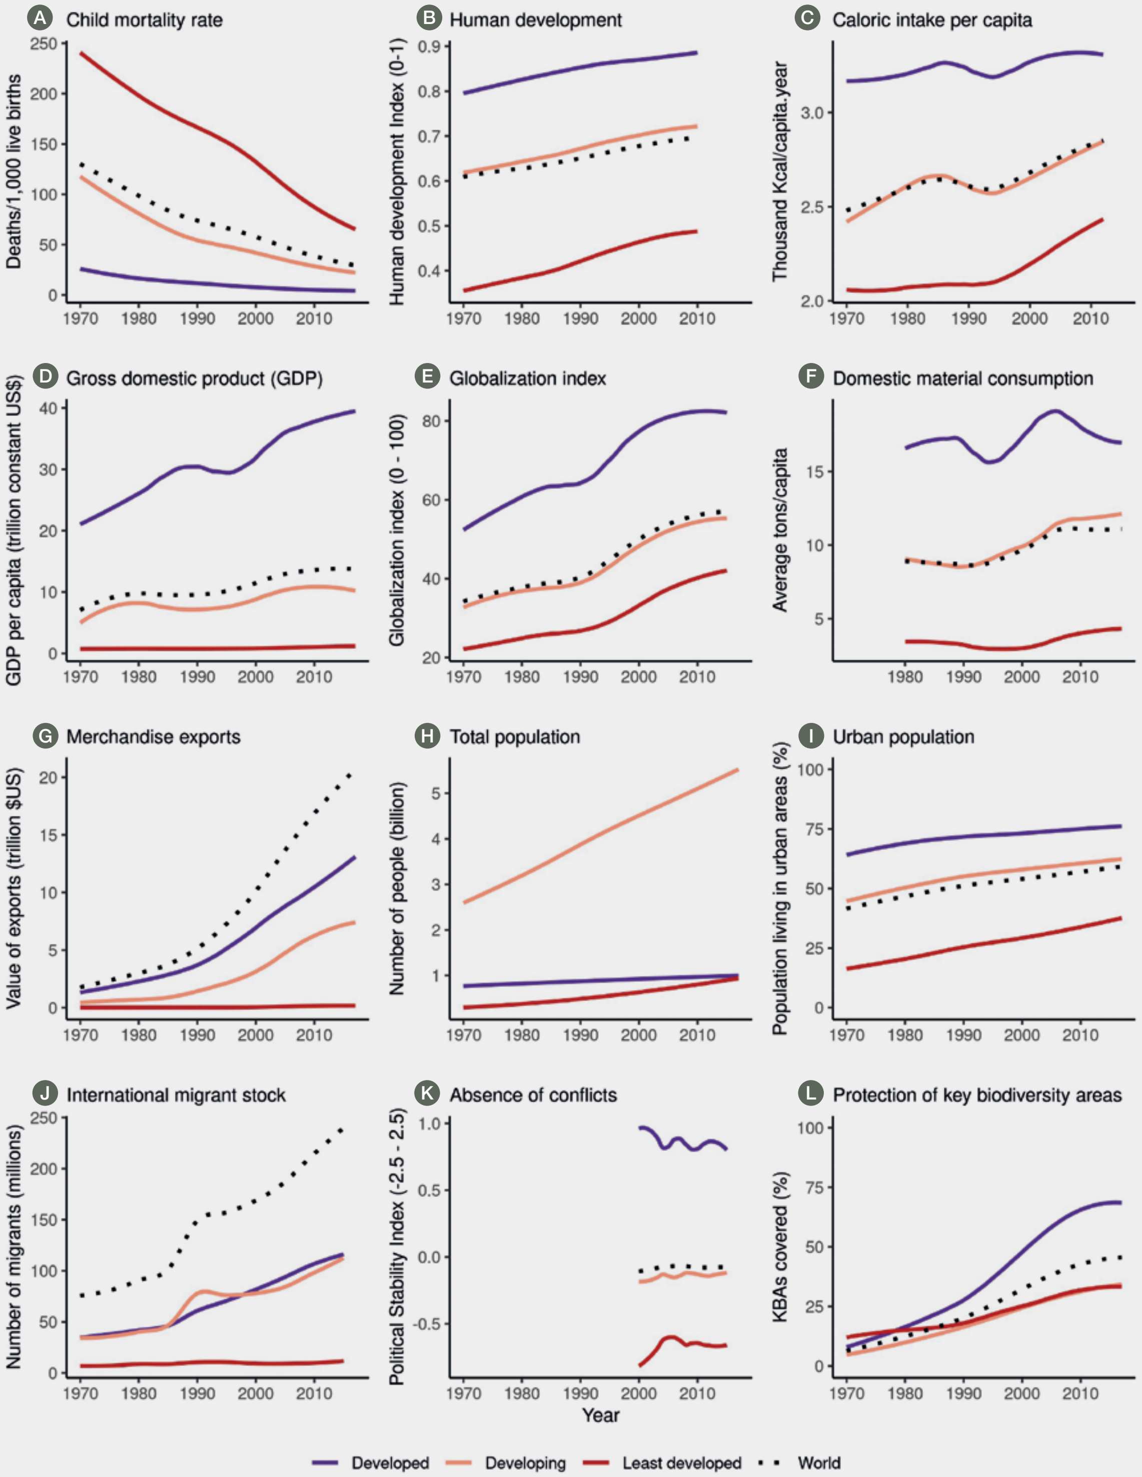

Figure 2 1 4 **Trends in indirect drivers for countries with different development levels.**

The data shown are trends, per country, averaged (A, B, C, D, E, F, H, I, and K) or totaled (G, J) for each of the three UN development categories: developed, developing, and least developed. Panels shown are: A **Child mortality rate:** Mortality rate, under-5 (per 1,000 live births); B **Human Development Index:** a summary measure of average achievement in key dimensions of human development: a long and healthy life, being knowledgeable and have a decent standard of living; C **Calorie intake:** Kilocalories consumed per person per day; D **GDP per capita** (gross domestic product divided by midyear population) in constant 2010 U.S. dollars; E **Globalization index:** The KOF Globalization Index measures the

economic, social and political dimensions of globalization; F **Domestic material consumption per capita:** all materials used by the economy, either extracted from the domestic territory or imported from other countries; G **Merchandise exports:** value of goods provided to the rest of the world per country valued in current U.S. dollars; H **Total population**; I **Proportion of urban population:** Proportion of the total population that is urban, which refers to people living in urban areas; J **International Migrant Stock:** the number of people born in a country other than that in which they live (includes refugees); K **Absence of conflict as an indicator of political stability:** Index that measures perceptions of the likelihood that the government will be destabilized or overthrown by unconstitutional or violent means, including politically-motivated violence as well as terrorism; L **Protection of key biodiversity areas (KBA):** measures progress towards protecting the most important sites for biodiversity in % of such sites per country (including Alliance for Zero Extinction sites).
Sources: BirdLife International (2018); FAO (2016a); KOF Swiss Economic Institute (2018); UNDP (2016b); UNEP-WCMC & IUCN (2018); World Bank (2018l, 2018i, 2018q, 2018k, 2018n); WU & Dittrich (2014).

biodiversity areas (KBAs). These global patterns will be described in detail in each of the sections of this chapter.

The trends differ widely, though, across countries, global regions, and regions within countries. To highlight some differences, we use a typology that divides all countries into three development level categories **(Figure 2.1.4)**: developed, developing, and least developed, based on Gross Domestic Product (GDP)[1]. We also use the four World Bank categories of income: lower, lower-middle, upper-middle and high income (World Bank, 2018r), that can be aggregated (lower-middle and upper-middle into middle) or disaggregated (high income OECD and high income oil and high income other) as needed (Figure S2). Additionally, we refer to the IPBES regions (Figure S2): Africa, Americas, Europe and Central Asia, Asia and the Pacific (see Supplementary Materials: Table 2 for a comparison of typologies).

2.1.2.2 Inequalities

2.1.2.2.1 Poverty and inequalities with respect to basic needs

There have been some marked advances in terms of poverty reduction over the past few decades (Figure S5), though many people around the world still remain in poverty. Per the "international poverty line" established by the World Bank in 2008, equivalent to a daily income below $1.90 US dollars/person (in 2015 prices) (Ravallion *et al.*, 2008), ~1.2 billion people still live in poverty (UN, 2016a). According to the Multidimensional Poverty Index (MPI), introduced in 2010 in the Human Development Report (UNDP) using metrics for health, education, and standard of living, still ~1.5 billion people are living in extreme poverty.

Further, even while overall income has risen on average to above the international poverty line, clearly many other basic needs have not been met, despite significant global stresses on nature. Globally, food security (i.e., security in food supply, with elimination of caloric and nutritional deficiencies) has been increasing but remains low within least developed countries. Currently, despite average gains over time at the global level, close to 860 million people still suffer severe food insecurity across the globe, of which 48% are in Africa (particularly in sub-Saharan Africa) and 45% in Latin America (Figure S3) (WFP, 2017). Conflicts, refugee crises, droughts, floods, pandemics, and inadequate social institutions all have contributed to shortfalls both in aggregate food production, or food availability, and in the effective food supply, with 37 countries (28 in Africa) having received emergency food aid in 2016 (WFP, 2017).

In addition, while the child mortality rate – largely associated with a lack of water sanitation and food deficiencies – has decreased overall, this threat remains prevalent in low income countries, in which as many as 10% of the children born alive die before age 5 (World Bank, 2018l). Regionally, Africa and the Americas show highest mortality (Figure S3). While access to improved water resources has increased, on average, 40% of the world's population still is lacking access to safe drinking water, most of them in least developed countries, especially within sub-Saharan Africa (WHO & UNICEF, 2017). Furthermore, almost all maternal deaths during childbirth (99%) occur in developing countries, over half in sub-Saharan Africa (Wang *et al.*, 2011), as a result of water scarcity, poor management, and governance failures.

In terms of broader measures of well-being, the Human Development Index (HDI) that includes income, health (life expectancy at birth), and education (average number of years of schooling) (UN, 2016a) also illustrates great contrasts across the planet. Least developed and developing countries have much lower HDI values than do the developed countries (**Figure 2.1.4**; UNDP, 2016a). Africa has the lowest HDI values among IPBES regions, followed by Asia (Figure S3). Across regions, Indigenous Peoples and Local Communities (IPLCs) are among the poorest groups, by income but also in access to basic needs, services, and opportunities (Hall & Patrinos, 2012).

Countries differ in many other well-being metrics too (**Figure 2.1.4**, Figure S4), such as material conditions for life – frequently assessed from an economic perspective with economic indicators (see section 2.1.3). Higher-income countries rank higher for indicators associated with societal

1. https://www.un.org/en/development/desa/policy/wesp/wesp_current/2014wesp_country_classification.pdf

development and for sustainability (Figure S4) (Eira *et al.*, 2013; Inuit Circumpolar Council, 2015; Raymond-Yakoubian & Angnaboogok, 2017), including for various indicators of the options citizens have, also called 'freedoms', that are included in the World Happiness Index (WHI, 2017) (Figure S4). These countries also have better conditions than low income countries for access, equality, tolerance, and inclusion of minorities, as shown by the Social Progress Index (SPI, 2017) (Figure S4). With respect to metrics for the management of ecosystem services and environmental policies such as Environmental Performance Index (EPI, 2018), low income countries rank lower. Yet they rank higher in terms of indicators for diversity, environmental degradation, and ecological footprint, including consumption of renewable water resources. Low income countries exhibit higher rankings in the Environmental Component of the Social Sustainability Index (SSI.EV; Figure S4) which includes linguistic diversity (Maffi, 2005), cultural identity, and the retention over time of indigenous ecological knowledge as well as practices (Sterling *et al.*, 2017).

2.1.2.2.2 Inequalities in Income

Economic inequality across all countries has been rising since 1820 (Bourguignon & Morrisson, 2002; World Bank, 2018r), and also has escalated since 1980 (**Figure 2.1.4**; Figure S2; Figure S3; Figure S5; World Bank, 2018o), with the highest-income countries increasing their incomes faster (OECD, 2015). In 2017, the GDP per capita was nearly four times higher in developed than in developing countries and nearly 34 times higher than in least developed countries (**Figure 2.1.4**; World Bank, 2018i). In terms of growth, GDP per capita is rising fastest for developed and developing countries, but slower in least developed countries, making the gap among these particular groups larger every year.

Within-country inequality also shifted over time in many countries. However, the changes went in both positive and negative directions, and so on average, within-country inequality remained fairly constant (Bourguignon & Morrisson, 2002; World Bank, 2018o). Still, quite a few countries experienced rising within-country income inequality, as expressed by metrics such as the Gini coefficient (Figure S5) or the Palma ratio (Palma, 2006), with cases in which lower incomes fell while higher incomes rose – particularly in the Americas and Africa.

2.1.2.2.3 Lifestyles and Inequalities in Consumption

Consumption too has been escalating, across the last few decades, albeit with differences among countries and global regions. Energy consumption has been rising since the industrial revolution. Wood and oil from whales were replaced in the early 1900s by coal, petroleum and natural gas (Smil, 2004). By the middle of the 20th Century, the "Green Revolution" boosted agricultural yields through the application of fertilizers, pesticides, fungicides and herbicides, together with irrigation, all of which increased energy demands (Dzioubinski & Chipman, 1999). Total energy use has doubled in the last 40 years (World Bank, 2018g) (Figure S6), while substantial transitions to modern gridded clean fuels occurred between 1990 and 2010 (Pachauri *et al.*, 2012), allowing ~1.7 billion people access to electricity and about ~1.6 billion people access to non-solid fuels for household cooking. The greatest increases have occurred in middle income countries, while low income countries exhibited lower increases (Figure S6; World Bank, 2018a) with real variations in rates of technological development and in the initial endowments of energy resources (Burke, 2010; Toman & Jemelkova, 2017). For instance, high income non-oil-producing countries have been gradually reducing their use of fossil fuels and increasing the use of nuclear and other non-fossil-fuel sources (Figure S7). Among the highest energy consumers, in total as well as per capita, are high income countries where intensive agriculture is more prevalent (Figure S9).

Global patterns of food consumption have also changed over the past fifty years, with important differences by country (Figure S6). As nations urbanize, urban dwellers get wealthier, food supplies increase, and eating habits change. Diets are rising in refined carbohydrates, added sugars, fats, and animal-based foods (e.g., meats, dairy) but falling in pulses, vegetables, coarse grains, fruits, complex carbohydrates and fiber, in tandem with the diversity of food sources (Keats & Wiggins, 2014; Khoury *et al.*, 2014; Popkin *et al.*, 2012; Tilman & Clark, 2014). Again, the variations across regions are significant. From 1970 to 2015, global average caloric intake per capita rose by 15% – yet developed countries have the highest levels **(Figure 2.1.4)**, particularly in Europe (Figure S3), while the lowest levels are found in least developed countries **(Figure 2.1.4)**, particularly in sub-Saharan Africa (Figure S3). Likewise, by 2009 while the average per capita consumption of protein exceeded the average estimated daily requirements in all the regions of the globe, it is the highest in high income countries (FAO, 2011b, 2016a; Paul, 1989; Walpole *et al.*, 2012).

With those changes in diet, the number of obese and overweight people has grown (Figure S6), to 2.1 billion in 2013 (Ng *et al.*, 2014). This too differs by region, with six times more obese people in high income than low income countries today (Figure S6). Furthermore, there are large variations across regions in the amount of fats (e.g., fats in foods and oils) for human consumption. The lowest quantities consumed are in Africa, while the highest are in parts of North America and Europe. Both the quantities and qualities (animal-based versus vegetable oils) of fats are key features of the nutritional transitions in national diets (Ranganathan *et al.*, 2016). Fast-food options are rising in low income countries, as exemplified by the higher numbers of chain restaurants (e.g., McDonald's restaurants[2]).

New 'needs' have also emerged with economic development. For instance, after mobile phones first became accessible, their number quickly "exploded" to one for every five people in the world (Figure S6). In addition to providing useful services, phones cause important environmental impacts associated with mining of precious metals for components and with both the manufacture of electronics and their careless disposal (Babu *et al.*, 2007; Fehske *et al.*, 2011; Wanger, 2011; Widmer *et al.*, 2005).

2.1.2.2.4 Inequalities in Environmental Footprints

With changes in lifestyle, per capita demand for natural resources has increased – unevenly (**Figure 2.1.4**, Figure S1). For instance, domestic material consumption (DMC) – the total amount of material directly used in an economy, including domestic extraction and imports (Wiedmann *et al.*, 2015; WU, 2017) varies greatly. DMC per capita is ~5 times larger in high income countries than low income. As DMC per capita rose by 15% globally since 1980 (18% since 1970), the largest increases are in developing countries (73% since 1970), followed by least developed (18% since 1970; **Figure 2.1.4**). By IPBES region, since 1980, DMC rose most in Asia and the Pacific (20%), followed by Africa (18%), and rose least in Europe and Central Asia (7%) (Figure S3).

Such demands upon nature scale with both the total population and demand per person. As such, since 1970, global material consumption has risen over 1.4 times faster than has total population (**Figure 2.1.4**, Figure S1). With every 10% increase in GDP, the average material footprint of nations – raw material extraction in the final demand of an economy – has risen by 6% (Wiedmann *et al.*, 2015; WU, 2017). Once again, growth rates for absolute and for per capita material consumption are unequal. For example, from 1980 to 2008 they increased in all regions except Central Asia (due to the collapse of the former Soviet Union) and most rapidly in Northeast Asia (Wiedmann *et al.*, 2015; WU, 2017). The global amount of material extraction was approximately 70 billion tons in 2008 (Wiedmann *et al.*, 2015; WU, 2017). Asia has the highest material extraction of all the regions, while 2008's per capita consumption in North America was ten times higher, at 30 to 35 tons of raw materials, than in Central Africa (Figure S18). Total material extraction (living and nonliving) in developing countries is rising the fastest, due to rapid increases in total population and GDP and DMC per capita (**Figure 2.1.12**, Figure S17, Figure S18, Figure S25).

All of this has impacts upon ecosystems. Estimates of ecological footprints, based on demands for both material and regulating contributions to people from nature, suggest sustained increases of footprints that are beyond the biological capacity to supply them (Borucke *et al.*, 2013; Galli *et al.*, 2016, 2014; Lazarus *et al.*, 2015; Lin *et al.*, 2015; Wackernagel *et al.*, 2014). This is especially true for the developing countries that are growing fastest in people, per capita demand, and globalization **(Figure 2.1.4)**.

Critically, environmental footprints of country consumption increasingly stretch beyond borders (as discussed in the introduction, see **Figures 2.1.2 and 2.1.3**). The world is ever more global, in economic, social, and political terms (Figure S1). Globalization metrics are highest for developed countries and lowest for least developed countries **(Figure 2.1.4)**. Such indices of increased resource flows include a 12-fold rise in the value of exports from 1970 to 2017, with fastest increases in developing countries (20-fold), followed by least developed ones (15-fold) **(Figure 2.1.4)**. Footprints associated with exports can be larger than is indicated by these trade values, though, because the usage of resources is, on average, larger than physical quantities of traded goods (Wiedmann *et al.*, 2015).

2.1.2.2.5 Inequalities in Social, Environmental, and Historical Constraints

Differences in current conditions and trends among countries are associated partly with different natural endowments. High income OECD countries and upper-middle income countries have the largest fractions of renewable freshwater resources and agricultural lands, for instance, while oil-producing high income countries have the smallest such fractions (Figure S7), although the largest for nonrenewable resources (e.g., petroleum, natural gas). Forest cover is similar for countries with rather different income levels, except for oil-producing countries that have little (S7). Globally, natural assets represent about one tenth of total wealth, with produced capital three times and human capital six times as large. Yet for some countries with lower income levels, the natural capital constitutes most of their wealth (World Bank, 2018o). The contribution of natural capital to total wealth for high income countries is relatively small, roughly half the magnitude of the shares for low income countries (Lange *et al.*, 2018a). Thus, degradation of nature should have the strongest detrimental impacts on low income countries' future economic development.

Beyond the roles natural conditions play in divergent development pathways among countries – which are debated (Diamond, 1997; Gallup *et al.*, 1999) – countries also differ in institutions, e.g., in governance, culture, religion, philosophies, and past development. The colonial period was characterized by natural resource flows from the South to the North that often were linked with

2. https://stage-corporate.mcdonalds.com/content/dam/gwscorp/investor-relations-content/supplemental-information/2016%20Restaurants%20by%20Country.pdf

ecological damage and social oppression (Goeminne & Paredis, 2010; Nagendra, 2018). As a result, tropical civilizations whose total wealth was closer to their European counterparts in the precolonial era are now far poorer (Acemoglu *et al.*, 2005). Patterns of poverty in the tropics have been linked to a variety of institutions, such as some arrangements that enable inclusive economic growth that lowers poverty (Acemoglu *et al.*, 2001; Easterly & Levine, 2003; Rodrik *et al.*, 2004). The current patterns of poverty and the environmental conditions in the Americas, Asia and the Pacific, and Africa are still strongly influenced by the pervasive experience of past colonialism (16th to 19th centuries). Its continuing influences upon resource flows and trade arrangements contribute to persistent social inequality as well as weak governance institutions which perpetuate inequalities (IPBES, 2018b).

For instance, most economic growth in the last 50 years occurred in countries not experiencing civil conflict and with strong state institutions. Additionally, 70% of today's poor live in "fragile states" with cycles of violence, weak institutions, inequality, and low growth. All are obstacles to overcoming poverty (Sachs, 2005; Smith, 2007; World Bank, 2015a). Developed countries are more politically stable **(Figure 2.1.4)**, e.g., with European countries more stable than African (Figure S3).

All these inequalities have important societal and environmental consequences – for instance, differential conservation practices, depending on governance contexts. Inequality is associated with less protected land for relatively democratic countries, yet the reverse is true for relatively undemocratic countries (Kashwan, 2017). Some suggest nonlinear linkages between inequality and both economic and environmental outcomes (Dorling, 2010, 2012; Holland *et al.*, 2009; Mikkelson *et al.*, 2007). Equality has generally facilitated collective efforts to protect natural resources under common and public ownership or control (Baland & Platteau, 1999, 2007; Bromley & Feeny, 1992; Colchester, 1994; Dayton-Johnson & Bardhan, 2002; Itaya *et al.*, 1997; Ostrom, 2015; Ostrom *et al.*, 1999; Scruggs, 1998; Templet, 1995). Inequality may yield social and environmental vulnerabilities, including through the distribution of risk (Bolin & Kurtz, 2018). Inequality may also lead to conflict and, if both become self-sustaining by limiting opportunities and mobility – yielding hopelessness and a lack of a vision – that can fundamentally undermine the motivation to invest in nature for sustainability (Stiglitz, 2013; Wilkinson & Pickett, 2010).

2.1.3 INDIRECT DRIVERS: VALUES

2.1.3.1 Different social groups hold different values

The different values people hold concerning nature, nature's contributions to people, and their relationship to the quality of life affect people's attitudes toward nature and, thus, the policies, norms, and technologies which modulate people's interactions with nature. Values encompass principles or moral judgments that can lead to responsibility concerning, and stewardship towards, nature. They also encompass varied views about the importance or significance of something or a particular course of action. For instance, as highlighted within 'the water-diamond paradox', even though water is necessary for life, while diamonds clearly are not at all, the market prices for diamonds usually are far higher due to (at times intentional) market scarcities (Chan *et al.*, 2016; IPBES, 2015; Pascual *et al.*, 2017a; see chapter 1).

Values concerning nature can be relational, instrumental or intrinsic (chapter 1). Individuals and social groups who hold in high regard their relationships with nature often hold moral principles for living in harmony with nature. Such relational values are central for Indigenous cultures in many parts of the world. This is the case, for instance, of the Eeyouch of the Eastern Subarctic in Canada, who traditionally view humans, other animals, plants, some aspects of the natural world, and spiritual beings as all having conscious agency in a world that is dependent on relationships and on an ethic of mutual respect (Berkes, 2012; Descola, 2013; Motte-Florac *et al.*, 2012; Pascual *et al.*, 2017a). Also, some groups in the Tibetan plateau hold that intangible and mythical creatures or deities inhabit soils, water, air, rocks and mountains, and have different qualities and identities with whom humans need to find a balanced mode of interaction (Dorje, 2011). Aymara and Quechua communities in the Andes, as groups elsewhere using this or other terms, conceptualize Mother Earth as a self-regulatory organism representing the totality of time and space and integrating the many relationships among all the living beings. Such conceptualization is used by many Indigenous organizations to re-establish cultural links to ancestral practices and to contest forms of environmental degradation that are imposed on them (Medina, 2006, 2010; Ogutu, 1992; Posey, 1999; Rist, 2002). Relational views such as these examples support approaches to governance that reaffirm important points of interconnection and virtues (e.g., respect, humility, gratitude) and often lead to self-imposed restrictions on use of nature (Mosha, 1999; Spiller *et al.*, 2011; Verbos & Humphries, 2014).

Instrumental values, in contrast, reflect the importance of an entity in terms of its contribution to an end, or its utility. Entities can provide instrumental value for consumptive (e.g., use of water, energy, biomass, food) and nonconsumptive (e.g., nutrient cycling) uses. Utilitarian paradigms viewing nature as a resource for economic development have intensified over the last centuries, especially in industrialized regions. In this anthropocentric, materialist worldview nature is seen as a pool of material goods and energies to be mastered and employed (Merchant, 1980; Nash, 1989; Pepper, 1996; Plumwood, 1991), supporting the extraction of biodiversity and resources (Dietz & Engels, 2017) and both substitutability and discounting perspectives. Substitutability implies that ecosystems or their functions could be lost as long as their contributions to quality of life are provided in other ways (Traeger, 2011). Discounting gives less importance in decisions to future benefits or costs (Dobson, 1999; Padilla, 2002) – following the assumption that future generations will be better off (much as current generations are better off than the past (above)).

In practice, values can be simultaneously instrumental and relational. Many Indigenous Peoples and Local Communities in varied rural settings, for instance – indeed across the IPBES regions – relate to nature with deep respect not only due to their conceptualizations of key relational values but also because their livelihoods depend upon the food and other materials that nature provides.

Intrinsic values are an inherent property of the entity (e.g., an organism), not ascribed by external valuing agents (such as human beings). Because of this independence from humans' experiences, intrinsic values are beyond the scope of anthropocentric valuation approaches (Díaz *et al.*, 2015). Intrinsic values can be particularly relevant in nature for non-human and even nonliving entities (Krebs, 1999). In the face of environmental degradation, environmental movements in the 1970s advocated for the intrinsic value of natural entities (Hay, 2002), regardless of their usefulness to humans. These included sentient animals (Singer, 1975), all living beings (Taylor, 1981) or ecosystems with living and nonliving components (Devall & Sessions, 1985). Intrinsic values have been presented as a basis for laws and regulations or other governance to implement conservation agendas that minimize humans' interactions with nature (Purser & Park, 1995) while ensuring the well-being of future human generations by maintaining nature's contributions to people (Mace, 2014). Some argue that the intrinsic value of non-human entities and its implications for biodiversity conservation could be considered as part of a wide instrumental perspective (Justus *et al.*, 2009; Maguire & Justus, 2008).

Nature is also valued today for its contributions into the future (Faith, 2016; UNEP, 2015), from a number of perspectives. Bequest values consider present-day satisfaction of protecting nature for future generations, for instance, involving a principle of intergenerational equity. Insurance values pertain to resilience, in the face of change, while option values facing uncertainty focus on retaining the potential to access nature's benefits in future (Gómez-Baggethun *et al.*, 2014).

Access to food, water, shelter, health, education, good social relationships, livelihoods, security, equality, identity, prosperity, spirituality, as well as freedoms of choice, action and participation, are valued in different ways by people in a society and across different societies (Díaz *et al.*, 2015). Some of these values may be expressed through the use of a standard of exchange used by a community, such as money. Monetary value is considered a proxy for how people may perceive the worth of an entity. Multiple considerations influence the estimation of an entity's monetary value – or the amount that people are willing to pay – which complicates the identification of its full significance. Due to the diverse ways of conceiving and experiencing the relationships between humans and the rest of nature, people also often value nature and nature's contributions to people, including many ecosystem services, in ways that are incompatible with the reasoning in monetary exchanges (Pascual *et al.*, 2017b; UNEP, 2015).

2.1.3.2 Values of nature are rapidly changing

The values at the core of individual and social priorities and behaviours also can evolve over time, informed by awareness, experience, culture and society. Pressures associated with globalization, climate change, and population migration over the last century have been catalysts for social and cultural changes – including changes in the human perceptions of and relationships with nature. While urbanization may separate people from nature, there is a trend towards greater awareness of the importance of nature to human well-being in the scientific community and across society.

Long-standing values held by communities with strong ties to the land are increasingly disrupted, however, by economic globalization (Beng-Huat, 1998; Brosi *et al.*, 2007; Jameson & Miyoshi, 1998). Varied global influences can challenge local practices, including in the implementation of conservation. Local conceptualizations of conservation may differ from external conservation paradigms (Miura, 2005), although perhaps even more from consumptive views on exploiting remote ecosystems. Changes in values and lifestyle include the abandonment of indigenous and local knowledge, and traditional practices (Halmy, 2016), the erosion of traditional knowledge (Youn, 2009), and changes in institutions and community organizations (Mburu

& Kaguna, 2016; Ole Kaunga, 2017), as documented by IPBES assessments (IPBES, 2018b).

Migration, domestic and international, can disrupt relationships between communities and lands if arriving attitudes are not adapted to local socioecological conditions. Migration (resulting from conflict, lack of livelihood, urbanization, industrialization of agriculture, and changes in climate, among other reasons) can lead to local and also global losses of local environmental knowledge, governance and management practices that sustained local livelihoods (Merino, 2012; Robson & Lichtenstein, 2013). Significant numbers of people changing locations has driven changes in the worldviews, values, and practices of populations that migrate as well as those that receive them.

Climate change itself can also lead to changes in practices and the values associated with them (beyond effects through migration). For instance, both farmers and fishermen have been forced to shift daily and seasonal practices that affect not only their livelihood outcomes but also their long-standing senses of place, community structure, and cultural tradition (Breslow *et al.*, 2014).

A new ethic regarding nature has been called 'environmental activism' to explicitly challenge the dominance of the instrumental values (Callicott, 1989; Dunlap & Van Liere, 1978; Guthrie, 1971; Leach *et al.*, 1999; Leopold, 2014; Levins *et al.*, 1998; Meadows *et al.*, 1972; Naess, 1973). Recent examples include Pope Francis' encyclical address (2015), reassessing Christianity's vision of humanity's relation with Earth (Buck, 2016; Marshall, 2009). Relational values also enter into conservation dialogues (Chan *et al.*, 2016; Mace, 2014). More holistic approaches to sustainable use of nature by humans inspired in part from indigenous worldviews are stated in international agendas, e.g., living in harmony with nature is a principle of the Rio 1992 "Summit of the Earth" (Mebratu, 1998; UN, 1992) and Rio 2012 Conference on Sustainable Development (UN, 2012) and the vision of the Convention on Biological Diversity up to 2050. An International Day of Mother Earth is recognized in the Rio+20 "The future we want" document, linked to rights of nature (UN, 2009, 2012). Recognition of Mother Earth appears in recent climate change agreements (UNFCCC, 2015), in the Convention on Biological Diversity (CBD, 2014) and in the United Nations Environment Assembly of the United Nations Environment Programme (UNEA, 2014).

More generally, Indigenous groups are actively trying to protect their rights while strengthening the recognition of the legitimacy of their relational worldviews and related governance practices in the face of economic, political, social and environmental pressures (Baer, 2014; Blaser *et al.*, 2004). For instance, viewing nature as part of social life, not property to exploit, is suggested by the inclusion of intrinsic rights of the natural world in the constitutions of Bolivia and Ecuador (Lalander, 2015). Yet placing the rights of nature on par with those of Indigenous communities may support or undermine indigenous control and raise questions about how rights are linked with responsibilities. In Bolivia, for instance, rights of nature have been given equal standing to the rights of ethnic groups, while in New Zealand, some native (Māori) communities have successfully fought to gain political and legal power over land-use planning (Menzies & Ruru, 2011) in ways that lead to new laws that recognize the spiritual connection of an Iwi (tribe) to their ancestral place and the legal personality of national parks and rivers (Salmond, 2014).

Views of what constitutes a good quality of life are also changing. A vision welfare based upon economic development and material well-being prevailed in academic literature until the 1980s (Agarwala *et al.*, 2014), yet concepts of well-being have integrated additional dimensions and focused more on experiences of people (Gasper, 2004; King *et al.*, 2014; McGregor *et al.*, 2015) and include their capacities and connections with nature (Sterling *et al.*, 2017), together with education and health, knowledge and skills, happiness and satisfaction. Equity, justice, security and resilience lenses are also increasingly being integrated in definitions of well-being, alongside the recognition of different types of knowledge about life and cultural identities (Sterling *et al.*, 2017). Evolutions of values can have important consequences for nature and its contributions, modifying not only material consumption patterns and but also governance.

2.1.4 INDIRECT DRIVERS: DEMOGRAPHIC

2.1.4.1 Population dynamics

The world's population has doubled over the last 50 years (**Figure 2.1.4**; Figure S1), and is still growing, although the growth rate has peaked (Roser *et al.*, 2017). There are over 7 billion humans today (PRB, 2014). Important reductions in growth rates have been observed in developed countries, while the fastest increases are in the least developed countries **(Figure 2.1.4)**, and in Asia and the Pacific (Figure S3). These differences in growth rates are consistent with a 'demographic transition': population growth rates increase as child mortality decreases, leading to increased life expectancy; then fertility and growth decrease, leading to falling population growth rates, as has already been observed within some regions (Fogel, 1986; Hirschman, 1994; Thompson, 2003). The demographic transition occurred over centuries in Europe but more quickly in some developing countries over the last few decades in a context of poverty and overexploited natural resources.

Demographic patterns have been linked with urbanization and with improvements in women's education, rights, and health that tend to reduce child mortality and to improve family planning (Caldwell, 2006; Galor, 2012). Developed countries have lower growth rates than developing countries. While convergence is expected, large differences may still remain for at least one century as some countries, mainly in Africa, may maintain high growth rates if current slow decreases in fertility continue (Clarke & Low, 2001; UN, 2004). Further, different 'demographic transitions' have been suggested, relating to shifts in partnership formation (cohabiting instead of marriage), values associated with childbearing decisions (ethics, politics, sex relations, education), and the postponement of parenthood. Their environmental impacts bear exploration (Lesthaeghe, 2014).

The world's population is aging, with consequences for resource consumption and management. The number of seniors – 60 years and above – is growing fast, while those above 80 are increasing even faster (McNicoll, 2002). Seniors are growing faster in urban than rural areas (McNicoll, 2002). Aging in rural areas has implications for the composition of rural labor forces and thus agricultural production patterns, land tenure, social organization in rural communities, and rural socioeconomic development. Such shifts over several decades in developed countries are now taking place in developing and least developed countries, challenging generational replacement that has been central for governance, environmental protection and sustainable use in rural areas. Shifts also highlight poor environmental quality, plus limited access to employment and services – especially for young people – within the rapidly growing urban areas of the developing world.

2.1.4.2 Migration

The amount of people who migrate to a new country has more than tripled in the last five decades **(Figure 2.1.4)**, with about 240 million people living today within a country where they were not born. The number of international immigrants currently is largest for developed countries **(Figure 2.1.4)**, as well as for Europe and Central Asia (Figure S3). The number is increasing fastest, however, within developing countries **(Figure 2.1.4)**, and also in Europe and Central Asia (Figure S3), where the number of migrants has increased fourfold between 1980 to 2010, in both regions.

International and within-nation migration has multiple drivers (Arango, 2017). Large contrasts in political stability, satisfied basic needs, and larger incomes are among some of these key drivers, particularly within the Middle East, South America and Asia. Migration may also be triggered by environmental conditions, with estimates of several million 'environmental migrants' today and with orders of magnitude increases in that group expected in the future (Laczko & Aghazarm, 2009).

Scarcities of resources (Hunter, 2005; Hunter *et al.*, 2005) and unfavourable conditions (Hunter, 2005) can shift populations (Lee, 1966; Todaro, 1969). Such degradation can interact with extreme events, such as those which caused the severe dust storms that occurred in American and Canadian prairies during the 1930s (Cook *et al.*, 2009), leading to the suggestion that migration could be one adaptive strategy for households facing environmental pressure. Rising temperatures have increased internal migration strategies in Brazil, Uruguay and South Africa (Mastrorillo *et al.*, 2016; Thiede *et al.*, 2016). Periods of low rainfall drove both internal and international migration in rural Mexico, particularly from municipalities with rain-fed agriculture (Leyk *et al.*, 2017). Crop failures driven by low rainfall also have fueled migration in Bangladesh (Gray & Mueller, 2012b).

Complex social-ecological interactions also underpin migration across different contexts (Black *et al.*, 2011). Villages and families with more resources (e.g., higher agricultural production) are more likely to engage in costly long-distance migration, as observed in rural Ecuador (Gray, 2009a, 2010), and northeastern South Africa (Hunter *et al.*, 2014). The role of gender is context-dependent (Gray & Mueller, 2012b), with: women's marriage-related migration falling by half during a recent drought in Ethiopia (Gray & Mueller, 2012a); while rural-urban migration increased due to deforestation in Ghana's central region particularly for young men more likely to find urban employment (Carr, 2005). Household characteristics are also important. In the Brazilian Amazon and in Southern Mexico, circular or iterative rural-urban migration is more likely for young adults, whose remittances often help to expand agricultural production (VanWey *et al.*, 2007). Community characteristics also matter, in particular social networks. In the context of Mexico-US migration, for instance, the impacts of environmental and resource risks, such as droughts, on migration are different for communities with expanded social networks due to migration histories (Hunter *et al.*, 2013).

While migration can be a strategy to reduce risks, much environmental migration is involuntary (Hunter *et al.*, 2015). Acute events, such as disasters (Fussell *et al.*, 2014; Lu *et al.*, 2016) and chronic events, such as regular droughts (Bates, 2002; Hugo, 1996; Renaud *et al.*, 2007), lead to involuntary migration. For instance, the disappearance of Lake Chad over the last few decades has been a crisis unfolding over the long term that has both internally displaced people (IPCC, 2007) and generated migrations to other countries (Fah, 2007). In Egypt, water pollution and desertification, with other resource scarcity, has driven migration (UN, 2016b).

The degree to which migration aids household adaptation depends upon specific vulnerabilities, such as the sensitivity of one's livelihood to climate (Warner & Afifi, 2014). Poorest households may be trapped by environmental change, lacking capital and increasingly unable to support even the sending of a migrant to provide remittances (Black *et al.*, 2011). For Bangladesh in 1994–2010, for instance, the poorest households were unable to use migration in response to flooding (Gray & Mueller, 2012b). The poorer also suffer higher exposures to environmental hazards (including climate-related), with fewer alternatives for settling in safer places. Thus, they endure more severe and long-lasting consequences (Blaikie *et al.*, 1994; Gray, 2009b; Gray & Mueller, 2012a; Gutmann & Field, 2010; IPCC, 2007).

Migration can have positive or negative environmental implications for receiving or for sending areas (Adamo & Curran, 2012; Curran, 2002; Fussell *et al.*, 2014; Unruh *et al.*, 2004). In areas sending migrants, depopulation may improve environmental outcomes such as regrowth of forests on abandoned land (Aide & Grau, 2004). Remittances back to sending areas may have positive environmental effects, if they reduce resource dependence by substituting bought goods for local production. However, this often can increase food vulnerability for those who remained. Alternatively, funds could have deleterious environmental effects, if used to expand investments in environmentally damaging practices, such as transformation of agricultural lands into urban and peri-urban parcels for real estate development (de Sherbinin *et al.*, 2008; Meyerson *et al.*, 2007). Migration may also hinder local generational replacement, weakening local environmental governance and resource management initiatives, particularly within the contexts in which global climate change poses strong local pressures upon natural resources (e.g., greater exposure of forests to pests and wildfires) that require local protection capacities (Merino, 2012).

In areas receiving migrants, mixed effects on nature are observed. For instance, migration to destinations with high-value amenities can raise resource and environmental degradation. In frontier mining, agriculture and ranching settlements, populations rise in ecologically sensitive areas (Joppa *et al.*, 2009; Wittemyer *et al.*, 2008), e.g., relocation of farm workers to cassava fields in Thailand (Curran & Cooke, 2008) or settlements of displaced individuals in northern Darfur, Sudan that are associated with lower vegetation due to the expansion of small farming (Hagenlocher *et al.*, 2012). Migration may also shift behaviour in receiving areas if individuals adopt attitudes from migrants. Recent immigrants to the U.S. exhibited greater concern for environmental issues than longer-term immigrants or native-born citizens (Hunter, 2000). Yet it has also been found that immigrants' perspectives about the environment can be at odds with resource management practices in receiving areas, as migrants are not very familiar with local realities and practices (Merino, 2012; Robson & Berkes, 2011).

2.1.4.3 Urbanization

Urbanization has been a significant trend in human settlement and development (**Figure 2.1.4**, Figure S1, Figure S3), driven by many factors and with significant environmental impacts. Globally, urban population rose from ~200 million in 1900 to ~4 billion in 2014 (UN, 2014), at which point over half of the world's population was urban. That share is expected to reach two thirds by 2050, as another 2.5 billion are expected to join urban areas, most in developing countries (CBD, 2012; Elmqvist *et al.*, 2004; UN, 2014). While the percentage of urban population is the highest in developed countries (~75%), it is growing the fastest in least developed and developing countries that rose 2.3 and 1.4 times respectively, respectively, between 1970 and 2017 **(Figure 2.1.4)**. Europe and Central Asia, and America have highest shares of urban population (~ 65% in each) but shares are growing the fastest within Africa (~40% between 1980 and 2010) and within Asia and the Pacific (~25%) (Figure S3).

Megacities with populations over 10 million people continue to arise and are projected to reach 41 by 2030. Small to medium-sized cities are growing the fastest and will be the home for the vast majority of future urban populations (UN, 2014). On the other hand, there are 300–400 shrinking cities in the world, about two-thirds in developed countries, in particular the United States, the United Kingdom and Germany (Kabisch & Haase, 2011; UN, 2014). Comparing IPBES regions, Africa, and Asia and the Pacific are urbanizing fastest, with future expansions in Asia and the Pacific expected to occur mostly in China and India (CBD, 2012; Seto *et al.*, 2011; Sui & Zeng, 2001). By 2050, up to 3 billion people will be living in slum areas within cities, mostly in developing countries (Nagendra, 2018).

Currently, urban areas cover under 3% of lands (Grimm *et al.*, 2008; McGranahan *et al.*, 2005; Potere & Schneider, 2007). Their extent is, however, expected to triple by 2030 (Seto *et al.*, 2012), rising faster than urban population. Much of the growth in urban extents has been observed in coastal regions, with 11% of all urban land in low-elevation coastal zones (i.e., less than 10m above sea level), where people and property are particularly vulnerable to floods and sea-level rise (Güneralp *et al.*, 2015; McGranahan *et al.*, 2007). In China, over 44% of urban land use is within floodplains, contributing to increasingly severe flood hazards (Du *et al.*, 2018). Rapid urban expansion is driven by positive feedbacks between urbanization and economic growth (Bai *et al.*, 2012), which generate further socioeconomic disparities between the coastal and inland regions (Bai *et al.*, 2012).

Urbanization is influenced by both ‘push’ and ‘pull’ factors (Hare, 1999), with job opportunities and services ‘pulling’ migrants while rural poverty, labor surplus, changing values (induced at times by the media and education), and civil conflicts acting ‘pushing’ people out of rural areas. ‘Push’ factors are often stronger, leading to many rural-urban migrants with poor employment and public services, including environmental. Poor neighborhoods in megacities of developing countries typically have poor environmental quality, with precarious access to safe drinking water and sanitation (Nagendra et al 2018). Yet the drivers of urbanization are quite variable (Bloom *et al.*, 2008; Fay & Opal, 2000), with important roles of national policies (Bai *et al.*, 2014). For instance, developed countries typically have higher levels of urbanization, with a strong correlation to productivity and income (Cohen & Simet, 2018). This forms a basis for some countries to promote urbanization as part of a strategy for economic growth, but there are large regional disparities, as well as quite mixed results (Bai *et al.*, 2012; Bloom *et al.*, 2008).

2.1.4.4 Human Capital

Human capital – including education, knowledge, health, capabilities and skills – is a significant component of development, one judged by many to be the largest share of the total wealth of all nations (World Bank, 2018o). That share varies by income level: within the low income countries, ‘produced and natural capital’ are the largest share; while in the high income countries, human capital dominates (World Bank, 2018o). Within that human capital, the levels and types of education influence economic development, including the scale of output, sectoral mix, and techniques used. Yet the relation between education, economic performance, environmental attitudes and sustainability is multifactorial – with factors such as economic and development policies, consumption patterns, and integration within the global economy playing major roles.

Human capital can be strongly affected, for instance, by the roles of women within a labor force. This societal factor can have a strong influence not only on the use of natural capital but also on other forms of human capital (World Bank, 2018o), beyond yielding more total human capital. Between 1995 and 2014, the estimated female share of human capital, globally, rose to ~40% – albeit with regional variations (from 18 to 44%; Credit Suisse, 2018).

2.1.4.4.1 Less Agricultural Extension

Meeting the world’s increasing demand for food while still reducing agriculture’s environmental impacts is one of the defining challenges of our times. Agricultural extension services constitute an important approach, as they may foster more productive uses of our limited natural resources, as in precision agriculture (Bongiovanni & Lowenberg-DeBoer, 2004). On the other hand, they can catalyse degrading shifts in production systems that lead to many losses of diverse traditional farming systems (IPBES, 2018b), or widespread harmful removal of tree cover (IPBES, 2018a).

During the 1960s and up to mid-1970s, rural support via agricultural extension was quite strong, particularly as associated with the Green Revolution. During the 1970s, extension was included explicitly within approaches to integrated rural development. However, public-sector extension became more limited after the 1980s, with its emphasis upon participatory approaches alongside drastic decreases in governmental expenditure on agricultural credits. In Latin America, between 1991 and 2007 such extension expenditures were reduced to below 10% (Figure S8). In addition, private support for such agricultural extension also started to decline around the 1980s, leading to underfinancing, staffing shortages, and the contraction of extension services (FAO, 2017b).

2.1.4.4.2 Indigenous and Local Knowledge

Indigenous Peoples and Local Communities (IPLCs) constitute a significant fraction of the world’s population and occupy a large fraction of the land area of the planet. Between 1 and 1.5 billion people are considered as members of Indigenous Peoples and Local Communities (see chapter 1), whiles estimates about smallholders range from 2 to 2.5 billion people (Zimmerer *et al.*, 2015). IPLCs manage or have tenure rights within ~38 million km^2, in 87 countries (or politically distinct areas), on all inhabited continents, covering over 25% of the land surface (Garnett *et al.*, 2018; Oxfam *et al.*, 2016). Their territories intersect with key areas for biodiversity conservation, including ~40% of all terrestrial protected areas and ecologically intact landscapes (Bhagwat & Rutte, 2006; Foltz *et al.*, 2003; Sobrevila, 2008). Traditional occupations are a key source of livelihoods and income for many IPLCs, thus recognizing their rights to land, benefit sharing, and the corresponding local institutions are crucial for supporting local to global biodiversity conservation goals (Garnett *et al.*, 2018).

Today, indigenous and local knowledge (ILK) is increasingly seen as relevant for sustainable resource use, not only for IPLCs but also more broadly. This reflects a shift from centralized, technically oriented solutions, which have not substantially improved the livelihood prospects for many small farmers (even if helping others). While there do exist multiple differences between indigenous and modern/contemporary knowledge, they still have some substantial overlaps, and ways to leverage the two sources of knowledge – e.g., for optimizing agricultural systems around agroforestry, multiple tree-cropping systems, and soil management targeted at smallholders – are being increasingly sought and further developed (Barrios & Trejo, 2003; Cash *et al.*, 2003).

Yet, the traditional practices stemming from ILK clearly are also declining at the very same time, and across multiple communities (Forest Peoples Programme, 2016; chapters 2.3 and 3). For instance, changes in both values and knowledge can be driven by contemporary education, in which prestige and progress might be associated to the replacement of traditional knowledge, which plays a key role in either the maintenance or the erosion of local worldviews and knowledge (Godoy *et al.*, 2009; Reyes-García *et al.*, 2007). More generally, schooling can loosen people's direct personal interactions with nature and lower traditional knowledge, while also potentially hindering the traditional transmission of knowledge based on direct learning from practice guided by local adults and elders. This occurs by creating cross-generational language barriers and changing cultural values (Godoy *et al.*, 2009; Pearce *et al.*, 2011; Reyes-García *et al.*, 2014, 2007). For instance, formal education can remove children from the everyday lives of families during the periods crucial for learning traditional knowledge (Ohmagari & Berkes, 1997; Ruiz-Mallén *et al.*, 2013), effective transmission of which relies upon observation, participation, and imitation in families and wider local communities. As formal education focuses on abstract and general knowledge, often alien to everyday life and local contexts, it may serve to overwrite elements of traditional knowledge. Thus, different ways of learning (i.e., traditional/local vs. formal) may result in multiple cultural identities (Pearce *et al.*, 2011). Yet, nonetheless, there are cases in which traditional knowledge and formal education have been successfully integrated, e.g., using local language and culture in implementing education and by also motivating traditional knowledge transmission (Barnnhardt & Kawagley, 2005; McCarter & Gavin, 2011; Michie, 2002; Ruiz-Mallén *et al.*, 2013).

2.1.4.4.3 Environmental Education

The patterns and relationships within human behaviours which are related to actions that affect nature started to be more closely assessed in the 1970s and 1980s (Hungerford & Volk, 1990). Results from systematic meta-analyses confirm that while environmental awareness is important, knowledge alone is not enough to motivate pro-environmental action (Bamberg & Möser, 2007; Klöckner, 2013). Also, pro-conservation and environmental attitudes tend to be insufficient for inspiring significant behaviours (Ajzen & Fishbein, 1980; Monroe, 2003; Schwartz, 1977; Stern, 2000). Instead, meaningful childhood experiences regarding nature, in particular in the context of family members who model care for nature, have been linked to adult conservation behaviours (Children and Nature Network, 2018; Clayton *et al.*, 2012; Tanner, 1980).

While a childhood's time in nature is clearly instrumental in developing a lifelong commitment to care for the Earth, a positive and meaningful connection to nature can also be facilitated and enhanced throughout our lives, though, and may start at any time. Nature-based activities have been shown to have instrumental influences on adult behaviour (Chawla, 1998; Wells & Lekies, 2006). Opportunities to cultivate that sense of connection can emerge within rural as well as in urban environments – not only promoting environment-supporting behaviours but also leading to increased health and well-being (Richardson *et al.*, 2016). Several studies have demonstrated a positive relationship between the level of involvement in nature-based activities as diverse as fishing (Oh & Ditton, 2006, 2008), SCUBA diving (Thapa *et al.*, 2006) and bird watching (Cheung *et al.*, 2017; Hvenegaard, 2002; McFarlane & Boxall, 1996), and individuals' concerns for the resources upon which their activities depend. People also grow attached to the specific places where they interact with nature, where they are more likely to engage in conservation actions (Halpenny, 2010; Ramkissoon *et al.*, 2013; Stedman, 2002; Tonge *et al.*, 2014; Vaske & Kobrin, 2001). For those already positive toward the environment, regular time in nature may play an affirming role by keeping nature "top of mind" and increasing the likelihood of taking action to benefit the environment (Manfredo *et al.*, 1992; Tarrant & Green, 1999; Thapa, 2010), all highlighting the importance of regular or even frequent experiences outdoors in nature (Kellert *et al.*, 2017).

2.1.5 INDIRECT DRIVERS: TECHNOLOGICAL

2.1.5.1 Traditional Technologies (Indigenous and Local Knowledge)

Both archaeological and contemporary evidence suggest that humans have used and continue to use a wide variety of deliberate means to manage species within habitats rich in biotic resources (Hoffmann *et al.*, 2016). Indigenous Peoples continue to interact with the planet's ecosystems in many and varied ways: forest managers in the tropical lowlands or in the mountains; pastoralists in savannas and other grasslands; and nomadic or semi-nomadic hunters and gatherers in forests, prairies and deserts (Toledo, 2013). Large groups of Indigenous Peoples are also just small-scale producers, not always easily distinguishable from the non-Indigenous Peoples producing nearby. Within the Andean and Mesoamerican countries of Latin America, the Indigenous Peoples farm much like surrounding small-scale farmers (Bellon *et al.*, 2018), with technology and knowledge flowing between the groups. Similarly, in India, distinctions between scheduled tribes and non-tribal peoples cannot be made solely upon the basis of productive activities. In these and other many cases, non-indigenous and indigenous producers plant crops using similar farming methods (Toledo, 2013), while also broadly contributing to dissemination of technologies and knowledge, such as in cases of agroforestry and other tree-cropping systems that are increasingly important within many regions (Agrawal, 2014). Together, IPLCs and a wide range of smallholder producers contribute a significant share of our global food production.

ILK and related practices are increasingly seen as relevant for sustainable use. This is part of a shift from centralized, technically-oriented resource management solutions that, in many cases, adapt poorly or are even harmful to local quality of life and environment. Beyond ecological knowledge and production technologies, there is increasing appreciation for the importance of local institutions that underlie the local access to, use of, and management of natural resources.

Indigenous Peoples and Local Communities' practices usually are based on a broad knowledge of the complex ecological systems in their own localities (Gadgil *et al.*, 1993). A wide range of outcomes emerge from these relationships, with cases illustrating sustainable resource and others with heavy ecosystem impacts via inappropriate management by local populations. For example, water use within Indian communities has proven to be highly efficient, for storage and distribution. Communities located close to the mountains with abundant precipitation have extensive knowledge about canals, dams, pools in hard rocks, and systems known as *kul*, *naula*, *Khatri* (Bansil, 2004). Indigenous Australians have demonstrated detailed technical knowledge of fire and have used it effectively to improve habitat for game and assist with the hunt itself (Lewis, 1989). Indigenous fire management has been documented across the world for agricultural and pastoral use, hunting, gathering, fishing, vegetation growth and abundance, clearing vegetation, habitat protection, domestic use, medicine/healing and spiritual use (Mistry *et al.*, 2016; Sletto & Rodriguez, 2013). In Brazil, the practice of Mayú, a mutual cooperation in the elaboration of large-scale tasks within traditional farming, e.g., cutting of trees and burning the felled biomass, is one social institution which has facilitated the formation and establishment of social bonding as well as important intergenerational knowledge transfer (Mistry *et al.*, 2016).

In tropical countries, IPLC agroforestry systems are based on ancestral practices with common characteristics. These systems are highly diversified, productive and complex. Producers manipulate species but also vegetation and ecological processes (Toledo & Barrera-Bassols, 2008). As within many regions of the world, in these countries the rotation of harvesting contributes to landscape heterogeneity – and while such rotation in agriculture is well known, less well known is rotation for grazing and hunting and fishing. In semiarid regions such as the fringe of Sahel, for instance, seasonal patterns of rainfall drive migration by larger herbivores and by traditional herding peoples. This can allow for the recovery of grazed lands – which can be disrupted by settlement. Throughout arid and semiarid Africa, traditional herders followed migratory cycles, rotating grazing land seasonally and, in cases, rotating adjacent grazing areas within a season (Gadgil *et al.*, 1993).

Yet, indigenous and local knowledge and practices are being lost, even as they come to the fore. One indication is reduced linguistic diversity. The Ethnologue (Lewis, 2009) identified 6,909 languages – of which half are at risk of extinction**.** Linguistic diversity can be correlated with biological diversity in regions including Taiwan and the Philippines, the Amazon Basin and Papua New Guinea and Eastern Indonesia, Northern and Central Australia, Eastern Siberia, and Mesoamerica. Extinction risks for these elements of linguistic diversity are high in Australia, the Amazon and Eastern Siberia. In many cases, these losses also correlate with the abandonment or transformation of local production systems, with implications for land cover change (involving reforestation and/or deforestation), local food self-sufficiency, and the loss of agrobiodiversity.

2.1.5.2 Technological changes in primary sectors (with direct uses of nature)

2.1.5.2.1 Significant Transitions in Agriculture

Agriculture has expanded significantly, in response to increasing demands – a trend not likely to decline in the near future, given the increases in livestock, human populations, and incomes. Yet such expansions can be either extensive, via increased area, or intensive, via increased yield (output per unit area, often increased through increases in the levels of inputs). At a global scale, intensification can imply greater shares of agriculture in some regions yet reductions elsewhere. Areas can fall while outputs hold steady, with increases in yields, as in high income countries in Latin America and the Caribbean (Figure S9). Illustrating regional variation, agricultural yields and areas rose concurrently in middle income countries, as well as in low- and middle income sub-Saharan Africa. For instance, there was a rise in both land area allocated to cereals and the cereals yield in sub-Saharan Africa, while other areas focused on raising yield without any significant increase in their farming areas. Most of the agricultural producers in this region are smallholders – including those farmers who practice slash-and-burn agriculture, which in some areas has contributed significantly to the losses of forest ecosystems and biodiversity.

Historically, the Green Revolution brought important changes with both opportunities and risks. During the 1960s, 1970s and 1980s, yields of rice, maize and wheat all increased steadily via the application of innovations in seed development, irrigation and fertilizer use. With billions added to the world population, since these practices began, many believe that without gains in outputs, famine and malnutrition would have been much greater. A nutrition expert who led the FAO, Lord Boyd Orr, was awarded a Nobel Peace Prize in 1949. The 'father' of the Green Revolution, Norman Borlaug, was also awarded a Nobel Peace Prize, in 1970, for 'providing bread'. Borlaug promoted the aggressive use of all advances in traditional methods – and then later championed genetic engineering – to develop varieties with greater yields, as well as resistance to diseases.

Yet, the Green Revolution highlights both the immense potential and significant trade-offs from innovations (Abramczyk *et al.*, 2017). Chemicals uses caused environment and health issues (Singh & Singh, 2000; WHO & UNEP, 1989; WRI *et al.*, 1992). Also, intensive fossil-fuel agricultural practices have negatively affected the water table in many regions. Food security fell for some, as production shifted out of the subsistence approaches which had been feeding many peasants in India. Also, monocultures have yielded poorer diets than traditional farming and agrobiodiversity. Looking globally, such practices also can lower food security through greater control of food systems by corporations upon whose inputs small- and middle-scale producers become dependent (Berlanga, 2017) and who may promote diets yielding poorer nutrition. Some practices may be subsidized by national governments, in the favour of large firms (FAO, 2009a). Also, despite food availability, famine has continued to come about, given societal failures (Drèze & Sen, 1991).

For nature, a gain from yields can be 'sparing' of land, i.e., less need for land for a given output (Stevenson *et al.*, 2013). Yet, evidence of land sparing is mixed across scales (local, national and global), intensification types (technology-driven versus market driven) and contexts (governance). Technology-driven increases in the outputs per unit area can reduce the pressure on land (Byerlee & Deininger, 2013) when intensification is far from frontier areas, so demands pull labor away from frontier areas. It can increase pressure by raising frontier productivity – increasing returns to lands (ibid). The market dynamics matter (DeFries *et al.*, 2013; Meyfroidt *et al.*, 2013; Rudel *et al.*, 2009b). For the IPBES regions, Africa responded to such increases in demands by increasing areas, while Asia and the Pacific responded mainly by increasing yields, using investments in both infrastructure and governance (IPBES, 2018b).

Potential adjustments to improve trajectories include applying IPLCs' agroecological innovations. Additional potential adjustments include various uses of biotechnology that, in traditional forms, have contributed for millennia. Providing foods and medicines via farmer selection and breeding of crops and animals has deep roots in local and traditional knowledge. Ongoing uses include a large number of plant varieties (for agrobiodiversity) and livestock breeds adapted to extremely varied soil, climate, disease, predation, and management contexts with specific qualities. These varieties and breeds constitute an asset to preserve for all of humanity, while modern agriculture has tended to homogenize the genetic diversity of crops and herds (see also chapter 2.2).

Further potential adjustments are genetically engineered seeds (genetically modified organisms -GMO) commercialized in 1996 and planted on ~185 million ha, across 26 countries, by 2016 (ISAAA, 2016) to increase insect resistance (IR) and herbicide tolerance (HT) in maize, soybean, cotton and rapeseed, thus lowering damages and crop losses (Lichtenberg & Zilberman, 1986). Hundreds of studies of farm-level impacts of HT and IR including field trials in many countries reveal substantial but not universal yield gain (Carpenter, 2010; Finger *et al.*, 2011; Qaim, 2009). Yet by increasing cotton yields 34%, corn yields 12% and soybean yields 3% such seeds are estimated to have spared 13 million ha of land from agriculture in 2010 (Barrows *et al.*, 2014b). Yield gains should be greatest in developing countries (Qaim & Zilberman, 2003), where pest pressures are higher, but smaller where pest damage is effectively controlled by conventional means (Carpenter, 2010; National Research Council, 2016; Qaim, 2009).

Evidence about lower pesticide and herbicide use due to such seeds is mixed. National Research Council (2000b) reported resistance in only three pest species in the first 14 years of commercial IR cropping, yet the cases have increased over time (Bennett *et al.*, 2004). The NRC (National Research Council, 2016) determined that damaging levels of resistance evolved in some insects targeted by IR crops where resistance-management practices were not followed. For instance, at least 10 species of weeds have evolved a resistance to glyphosate within the United States due to a nearly exclusive reliance on it for weed control (Duke & Powles, 2009). The situation may be improved by uses of varied weed control mechanisms (Barrows *et al.*, 2014a). Overall, as for other innovations, trade-offs emerged for genetically engineered seeds – including increasing costs, though control costs can decline sufficiently to improve farms' margins (Carpenter, 2010).

Trade-offs for GMO seeds might also include environmental concerns, such as impacts on crop genetic diversity, people's health and farmers' livelihoods. Gene flows across GMO and non-GMO seed can result from cross-pollination between GMO and non-GMO plants from different fields, as confirmed for the case of some landraces of maize in Mexico by a board of scientists (Commission for Environmental Cooperation, 2004), thus suggesting more attention is needed (National Research Council, 2010). Genes can also be transferred to wild plant species belonging to the same genus, which may have unpredictable effects. In terms of health, use of the herbicide glyphosate has been linked to an increase in cancer rates and teratogenesis in Argentina (Vazquez *et al.*, 2017) and some data suggest accumulations within the animal and human food chains (Krüger *et al.*, 2014) – yet the US NRC did not find evidence that consumption of GMO foods is riskier than non-GMO counterparts (FAO, 2000; National Research Council, 2000a, 2000b; WHO, 2005). Economic benefits and costs have been documented in varied contexts (Brookes & Barfoot, 2012; Kathage & Qaim, 2012; Qaim & de Janvry, 2003; Qaim & De Janvry, 2005; Zambrano *et al.*, 2009) yet there can exist concerns even about the economic and political pressure upon such science itself.

2.1.5.2.2 Limited Transitions in Biomass Energy

Innovation has also occurred in how energy is produced and used. More than in any other region, though, households in sub-Saharan Africa still depend upon biomass for domestic energy supply – with effects on health and nature (Arnold *et al.*, 2006; Bailis *et al.*, 2015, 2005; Foley, 2001; Ramanathan & Carmichael, 2008; Vlosky & Smithhart, 2011), particularly within East Africa. Approximately 95% of the people in Burundi, Ethiopia, Rwanda, Tanzania and Uganda use solid fuels to cook and to heat (GACC, 2017). Persistence within such behaviours is due in part to societal values of fuelwood, the slow development of markets for modern fuels (e.g., liquid petroleum gas) and clean cookstoves, with little information on personal or social benefits of switching fuels and stoves (Masera *et al.*, 2000; Schlag & Zuzarte, 2008). High capital costs and poor infrastructure have both also further inhibited the household adoption of modern fuels and technologies (e.g., electricity). In western Uganda, fuelwood consumption has contributed to deforestation (Dovie *et al.*, 2004; Ndangalasi *et al.*, 2007; Nkambwe & Sekhwela, 2006)though small-scale agriculture and timber remain the primary drivers (Geist & Lambin, 2002; Jagger *et al.*, 2012; Mwavu & Witkowski, 2008). Outside parks, half of tropical forest on private land is degraded (Nsita, 2005) in part to gain *de facto* property rights (Jagger, 2010).

Land-use change has greatly lowered the standing biomass over quite a short period of time (e.g., 26% in 2003-11). This can induce the planting of trees, as a response to scarcity of biomass. Yet it is only at small scale. Greater responses by rural households are in quantity and source of fuels – with significant shifts away from fuelwood from the forests to fuelwood from non-forest areas, which are larger where significant conversions have lowered biomass (Jagger & Kittner, 2017). More use of crop residues is consistent with this sort of shift. Shifting fuel types and sources has at least two direct impacts, at the level of a household: an increase in the use of low quality fuels, which raising exposures to household air pollution (Forouzanfar *et al.*, 2015); and an increase in the time required to collect fuel, with women primarily bearing the cost (Jagger & Kittner, 2017).

2.1.5.3 Technological changes, and trade-offs, within urbanization and industry

Transport investment and other innovations facilitated urbanization, generating both productivity – as economies diversified into manufacturing and services – and many other consequences. At the landscape level, transport investments also improved market access for peripheral areas. Still, most gains may go to urban areas and the linkages can further raise concentrations (Scott, 2009).

Within cities, transport costs again are critical. Given relatively fixed land areas, scale economies with high density eventually can be offset by congestion, i.e., traffic with time costs, so another urban investment has been in subways (Scott, 2009, chapter 4). Densities also raise the challenges of disease (Scott, 2009, pp. 140–141). Innovations such as vaccines address many threats, including in low income settings today, as do investments in sanitation that still affect choices of locations.

For direct uses of nature, scarcities have motivated innovations, including reductions in material or pollution intensities per unit production. Changes are due to both purely private motivations or regulations (see governance below) and, as consumptions rises, are needed to meet basic needs without raising consequent degradation. As consumers and as citizens, people may be willing to incur costs for cleaner production. For instance, households might on their own invest in stoves (Chaudhuri & Pfaff, 2003; Pfaff *et al.*, 2004a, 2004b; and many studies cited in World Bank, 2007) to produce cooking, heating and lighting services with far less pollution. This applies in rural areas but also has significant spillovers to ambient air quality within cities.

Scarcities of water quality and quantity clearly have motivated innovations, e.g., to purify water (Jalan & Somanathan, 2004) or to find safer sources (Madajewicz *et al.*, 2007). Understanding risk is critical for investments in both piped water (Jalan & Ravallion, 2003) and bottled (Fetter *et al.*, 2017). For water quantity, as for irrigation, at the local and community levels water shortages lead to social innovations such as local upstream-downstream groups to allocate water, as in Sri Lanka (Uphoff, 1996). Analogously, Ostrom (1990) documents a Spanish community's innovations to make water-use reductions physically and socially feasible, despite outputs goals.

Enormous shifts in energy efficiency are occurring, including in renewable energy. High prices for fossil fuels motivate such investments – just as recent lower prices for fossil fuels reduced the intensities of both conservation and exploration. Higher costs such as for extensions of electricity grids on rural frontiers also motivate investments in substitutes, such as solar, that degrade less. The diffusion or spreading of such innovations during industrial development can help nature (Popp *et al.*, 2010) and motivate further investments into research and development (Chuang, 1998; Golombek & Hoel, 2004). Broader use of such innovations could avoid the most environmentally destructive elements of economic development (Carson, 2009; Munasinghe, 1999), allowing 'leapfrogging' to modern technologies, e.g., grid or solar electricity, to furnish urban centers (Liu *et al.*, 2016a). Such diffusion may require regulation (Popp *et al.*, 2010) or subsidies to flourish (Fu *et al.*, 2011; Goldemberg, 1998; Murphy, 2001) yet in cases diffusion could even facilitate economic development (Munasinghe, 1999; Popp *et al.*, 2010) – including within fast-growing economies (Jayanthakumaran *et al.*, 2012).

Yet, as for other innovations, there are trade-offs including for nature – e.g., fossil fuel emissions from cars to windmills that hit birds. Replacing fuelwood with hydropower clearly aids forests and indoor air quality (Liu *et al.*, 2016a) but shifts water flows and flooding, with negative effects on biodiversity and more (Bunn & Arthington, 2002). While antibiotics have saved lives for over a century, and long been used in animal production, aquaculture, and high-value fruits and vegetables (McManus *et al.*, 2002) as well as feeds (Holmstrom *et al.*, 2003; Kumar *et al.*, 2005), they enter the soils plus surface and ground water and drain to coastal bodies of water where they do not readily degrade (Holmstrom *et al.*, 2003). Their widespread overuse also has led to a proliferation of antibiotic-resistant bacteria (Holmstrom *et al.*, 2003; Kumar *et al.*, 2005; McManus *et al.*, 2002) to the point of being recognized by the World Health Organization as a major, global public-health problem.

2.1.6 INDIRECT DRIVERS: ECONOMIC

2.1.6.1 Structural Transition

2.1.6.1.1 Economic Composition (shifts across sectors)

Since 1950, economies have shifted out of agriculture and towards both industry and services, in varied mixes. It is clear **(Figure 2.1.5)** that agriculture's share of value added is higher for low- than for high income countries, while the opposite ranking of shares holds in manufacturing and services.

For low income countries, employment shares across sectors were stable between 1990 to 2016 at ~65% in agriculture, ~9% in industry and ~26% in services. Across the same time period, however, the share of employment in agriculture fell 10% for all the middle income countries (down from ~46% in the lower-middle income and ~27% in upper-middle income countries), while the employment share in industry was relatively stable, rising about 4% during this period. Thus, employment went into services, which rose to ~37% in lower-middle and ~61% in upper-middle income countries, while also rising about 10%, to 73.1%, within high income countries.

Shares of GDP had similar trends, with agriculture falling for all country groups – albeit earlier for the high income but more smoothly for the middle income countries, stabilizing near 9% for upper-middle- and 16% for lower-middle income countries. From the 1960s, industry shares of GDP rose more steeply in high income countries, peaking at about 50% in 1974 while stabilizing at around 20% in low income and ~30% in middle income countries. Service shares increased steadily as well, reaching ~50% in low income and 63% in middle income countries by 2016. For high income countries, after fluctuating, they rose steadily until stabilizing around 68%.

According to the Vienna University of Economics and Business (WU, 2017), industrialized economies in Europe and North America have lowest material intensities (at 0.5 tons of material consumption per US$1000 of GDP in 2013, down from 0.8 and 1 in 1980, respectively). While this can be driven by technology shifts mentioned above, and by increased trade mentioned below, it **(Figure 2.1.6)** is partially due to the shift towards services.

Yet, scale still matters. Since 1950, world population grew by a factor of 2.7 and global material consumption by a factor of 3.7 (Schaffartzik *et al.*, 2014). Furthermore, resource use is unequal, linked to poverty. Western industrial countries that shared 44% of global GDP and 15% of world population in 2010 have been responsible for almost half of the global material consumption. In recent decades, there has been a shift toward China (Muradian *et al.*, 2012).

That shift in relative scales interacts with unequal intensities **(Figure 2.1.6)** to modify global intensities. Expansion in Asia raised average material extraction intensity for the global economy **(Figure 2.1.6)**, although without 'decoupling' the degradation of nature from economic growth (WU, 2017): while Asia's material intensity remained relatively constant for almost two decades after 1980 (at around 2.5 tons per $1000 US GDP), that measure rose (to 3.1 tons in 2013). African economies still have highest intensities but their improvement since 1980 (from 4.2 to 3.3 tons) has also been significant.

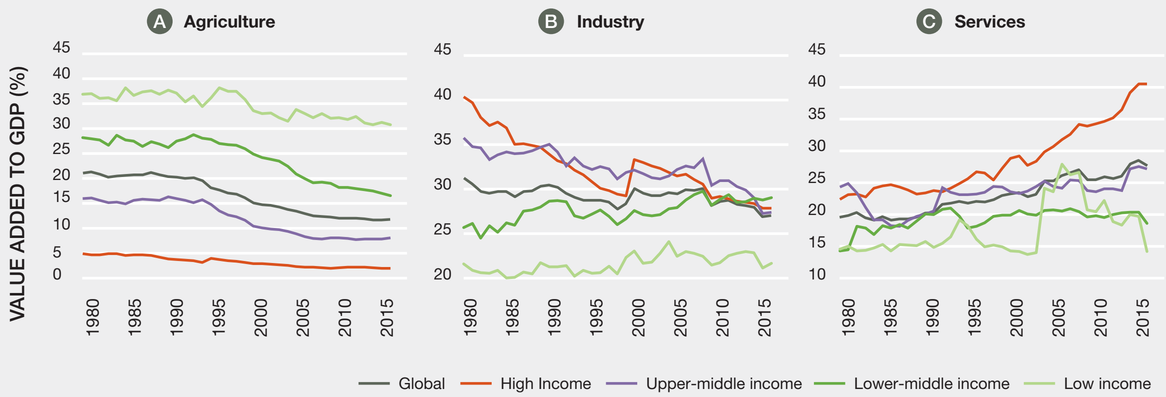

Figure 2 1 5 Changes in economic composition: Value Added in Agriculture A versus Industry B and Services C.

Values per country are averaged for World Bank income categories. Services sum service exports and imports then are divided by GDP, all in current U.S. dollars. Sources: (World Bank, 2018a, 2018b, 2018c, 2018d, 2018e)

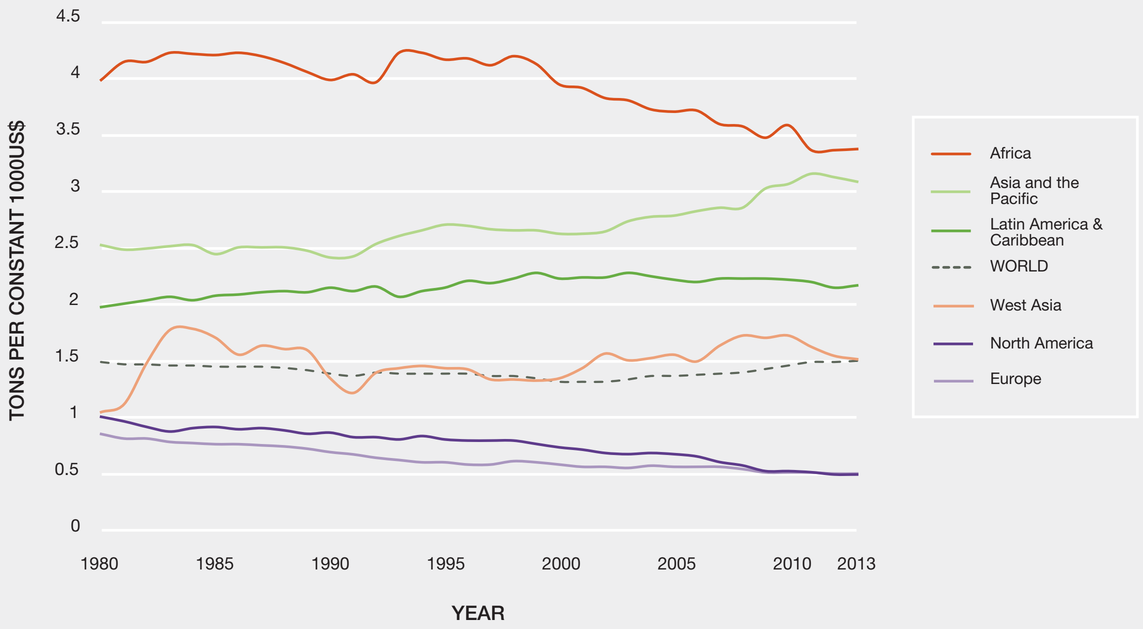

Figure 2 1 6 **Trend of material intensity (domestic material consumption in tons per constant 2005 US$1000 of GDP) by world region (1980~2013).**

Average values for six world regions and the world average for the tons of extracted materials necessary to produce economic output (in 1000 constant US $). 2.1.6.1.2 Factors Supporting Sectoral Shifts

Concerns about degradation are one motivation for individuals to put resources into transitions, such as across sectors. Such concerns or values are suggested when people take costly actions to maintain or to improve natural assets (e.g., Atkinson *et al.*, 2012; Freeman *et al.*, 2013; Merino & Martínez, 2014; Smith, 1996), e.g., treat water or use improved cooking technologies (Alberini *et al.*, 2010; Pattanayak & Pfaff, 2009), conserve ecosystems (Ferraro *et al.*, 2012; Kramer, 2007; Majuru *et al.*, 2016) and forests (Merino & Martínez, 2014). Scarcity of nature shifts the value placed on nature, as in the 'diamond-water paradox' (Farber & Griner, 2000; Heal, 2000): water is essential to sustain life yet, when perceived as plentiful, is used in non-conserving ways (Barnett & Morse, 1963; Pratt & Zeckhauser, 1996). Willingness to incur costs to shift behaviours also depends upon the belief that costs will be shared among interested parties and have positive outcomes. For instance, if families perceive that others free-ride on their actions, not engaging in contributions but benefiting, they too might free ride (Graves, 2009; Matta & Alavalapati, 2006; Starrett, 2003). Still, given a chance they may vote for rules that bind behaviours (Álvarez-Farizo *et al.*, 2007; Starrett, 2003; Wilson & Howarth, 2002; Wiser, 2007).

Beliefs about or perceptions of risk across sectors can help to drive such economic transitions (Lubell *et al.*, 2007; Whitehead, 2006). It can be hard to ascertain environmental quality, resulting in misaligned perceptions of safety and incorrectly low demand for actions that support nature (Orgill *et al.*, 2013). Salient information about the lack of environmental quality can spur demands for adjustments (Brown *et al.*, 2015; Hamoudi *et al.*, 2012; Madajewicz *et al.*, 2007). Within the provision of such information, one key issue is the multidimensionality of environmental amenities or, more generally, nature. For example, dimensions of drinking water that can affect behaviour include: price, convenience, reliability, taste, turbidity, and more (Farber & Griner, 2000; Jeuland *et al.*, 2016, 2014; Ma & Swinton, 2011). As a result, offering information on water's reliability alone may achieve little if other features affect decision trends.

When markets perceive scarcities, price rises, providing incentives to invest, as in forests (Foster & Rosenzweig, 2003), while countries may respond with policy (Mather, 2004; Mather & Fairbairn, 2000; Mather *et al.*, 1999a); for example, Bae *et al.* (2012) argue that South Korea's forest transition was due in some measure to reforestation policies. A different dynamic is a buildup of human capital that facilitates a switch to industry (Choumert *et al.*, 2013; Mather *et al.*, 1999a). Hecht *et al.* (2015) highlight the roles of urbanization and remittances in behavioural shifts (e.g., farmers migrate to the cities), while if populations stabilize, implying less growth in demands for crops, and in labor supply for agriculture, that can result in reduced pressure for new deforestation (Angelsen, 2007; Wolfersberger *et al.*, 2015). For instance, Rudel *et al.* (2000) found that for Puerto Rico, non-farm jobs pulled labor out of agriculture; agricultural production could then become more intensive, which could reduce the pressures on forests, while some agricultural lands could revert to forest (Rudel *et al.*, 2005). This lower pressure on forests can also result from a reduction of fuelwood collection (DeFries & Pandey, 2010).

2.1.6.1.3 Implications for Nature of Sectoral Shifts ('composition effects')

Sectoral shifts affect nature. A substantial literature during the 1990s found relationships between pollution concentrations and GDP per capita using data since World War II: as GDP per capita increases, pollution concentrations rise then fall (Gale & Mendez, 1996; Grossman & Krueger, 1991, 1995; Hilton & Levinson, 1998; Selden & Song, 1994; Shafik & Bandyopadhyay, 1992). In general, however, it appears that the specific relationships between pollution and economic growth can be quite different across the many types of pollutants, including in that they can be sensitive to the period of study and the quality of the data (Carson, 2009; Harbaugh *et al.*, 2002; Stern, 2004; Stern *et al.*, 1996). This speculative relationship was labeled the 'Environmental Kuznets Curve' (EKC, as a reference to Simon Kuznets' ideas in the 1950s about patterns of economic inequality for economic growth).

Parsing such patterns, Copeland and Taylor (2013) distinguish a few underlying changes that occur with the growth of an economy. Thus, when considering policies to shift outcomes, one might focus on any of these dimensions. The 'scale effect' refers to effects of the amount of production. The 'composition effect' refers to a change in the mix across types of economic activity – recalling that such changes in the sectoral mix could occur in part as a result of international trade. Last is the 'technique effect' that can apply to any type of economic activity, in which for private reasons and due to public policies innovations, as discussed above, there are lower damages per unit output for any sector (Brunel, 2017; Grether *et al.*, 2009; Shapiro & Walker, 2015). Some studies evaluate whether international trade induces such effects (Cherniwchan *et al.*, 2017; after Antweiler *et al.*, 2001; Cole & Elliott, 2003; Levinson, 2009; and Managi *et al.*, 2009).

These three effects can sum up to reverse trends for nature. One example of nonlinear and trend-reversing behaviour during economic development has been forest cover, i.e., 'forest transitions' (Mather, 1992). Various such sequences have been observed across the globe (Belay *et al.*, 2015; He *et al.*, 2014; Mather, 2007; Mather *et al.*, 1999b; Meyfroidt & Lambin, 2011; Rudel, 1998; Rudel *et al.*, 2002). While these forest cases do differ, their commonality is that in each case the trend in land use has been reversed (Barbier *et al.*, 2017) due to shifts in human choices, given changes in decision conditions. **Box 2.1.1** highlights the importance of understanding these dynamics well.

2.1.6.2 Concentrated Production

Corporations and financial agencies now control amounts of financial capital, which rival the revenues of the vast majority of countries. The top nine largest economies are countries but at least one company on its own could be the next largest, with larger revenues than the economies of India, South Korea or Australia (Anderson & Cavanagh, 2000). Another five corporations are, then, among the 22 largest 'economies' using these measures of size. One oil company, for instance, has a larger 'economy' than Mexico, India or Sweden. This size can affect the bargaining over any number of exchanges, from contracts with laborers to the exchanges of varied goods in which nature is embedded.

Box 2 1 2 **Examples of supply chain concentrations relevant for uses of natural resources.**

Coffee Despite variations, coffee beans have long been viewed as an undistinguished commodity. Around 70% of coffee is grown in farms under 5 ha (Fitter & Kaplinksy, 2001), so market power is at the other end of the supply chain: 10 global importers control over 60% of global trade. In some countries, buyers collude to drive down prices. Similarly, roasters are highly consolidated, e.g., five European companies controlled over 58% of the market in 1998. This affects governance of the chain and revenues by stage. Producers' prices remained flat or fell slightly over time while consumer prices increased and, in 1995, only 40% of the price stayed in the producing country to be split between producers and traders, implying at best zero rents at the start of the supply chain (Fafchamps & Hill, 2008; Fitter & Kaplinksy, 2001). A survey in Uganda in 2003 showed that the volatility of farm-gate prices did not reflect world prices, consistent with local traders exploiting small farmers' relative lack of information. Recently, though, the industry gives more attention to some of the characteristics of production locations. That can shift some market power to producers changing local communities' incentives to invest in nature and shifting the trade-offs from using it.

Horticulture (fruits and vegetables) Similar results hold in horticulture – boosted by transportation and refrigeration

Box 2 1 2

technologies. Many developing countries with geographical advantages in fruit and vegetables supply, including in Africa, try to reach European markets. Yet, European food retailing is extremely concentrated with the top 5 supermarket chains serving approximately 50% of the market in 1996, with producing countries capturing only 40% of the value. Europeans' demands for higher phytosanitary, social, and environmental standards – plus high predictability – helped out the larger exporters as well. In Kenya and Zimbabwe, for instance, few individuals and companies had capital to export (Dolan & Humphrey, 2000) and such opportunities made them more productive and also more successful within their domestic markets (Pavcnik, 2002). For flowers, recent technological innovations supported expansions by the traditional producers. Ecuador possesses advantages with year-round supply and cheap labor – yet without producer cooperation and differentiated products these advantages do not yield market power. If flower producers are not aware of final market conditions but informed by few importers, they get small profit shares. These dynamics affect the linkages from consumption to degradation and its local net benefits.

Textiles and Apparel In the 1980s, Mexican producers of blue jeans, for instance, moved from serving a small domestic demand to serving the US by partnering with 4 major manufacturers (Bair & Gereffi, 2001). By 2000, several top US retailers joined them, expanding the market. However, the fairly homogeneous nature of their output and a reliance on external inputs was conducive to only small rents, spurred an attempt at upgrading into marketing and design via their own brands. Yet, as in African horticulture, only the few most productive and capitalized firms could manage this. That increased market power and concentrated rents for a domestic elite (Bair & Gereffi, 2001) – while pushing down wages, which exacerbated domestic inequities. The textiles trade used to be driven and governed by cotton producers. However, consolidation of retailers shifted the governance of the supply chain downstream. Thus, cotton producers have shifted to trying cottonseed processing, where market power is not so menaced by international competition and shifting demands (Hutson *et al.*, 2005). Generally, shifts in the power between retail, upstream, and intermediate actors are important for understanding growth implications for the newly industrialized economies (Conway & Shah, 2011). Many developing countries are exporting textiles given foreign requirements that could boost internal productivity. Yet, in terms of surpluses earned, this may raise in-country surplus yet not help cotton per se. All of the dynamics are important determinants of the economic and environmental trade-offs faced, an understanding of which in this case can greatly inform policies focused upon water pollution.

Furniture (forests upstream) This chain has five main stages: forestry; sawmills; manufacturers; buyers and retailers. Demand shifts and retailer innovations raised retail competitive pressures and buyer concentration (Kaplinsky *et al.*, 2003). Traditionally labor intensive, this chain has a trend of falling prices, driven by rising competition and global price convergence with global sourcing (Kaplinsky & Readman, 2005). Buying is now done by a few actors who control higher-value-added activities such as marketing, design and after-sales service. Manufacturing is heterogeneous. South African producers are traditionally large, yet Kaplinsky *et al.* (2003) note declining prices due to the better competitive positions of buyers and suggested shifting into a different value chain (Saligna wood), with varied uses that allow entry with higher unit prices. Ivarsson and Alvstam (2010) examined firms' subcontractors in China and South East Asia. Over half sell over 60% of output to one firm, whose bargaining power implies a larger share of surplus, consistent with Gereffi *et al.* (2005) since the captive supplier is subject to the market power of that 'lead firm' (see also taxonomy in Milberg, 2004). Which chains suppliers sell into greatly changes their incentives for conservation of nature.

Large financial players also have emerged*.* Those include private equity investors, such as infrastructure investment funds, or institutional investors, such as pension and mutual funds (particularly mandatory pension contributions), all attracted by opportunities including the large infrastructure developments (Arezki *et al.*, 2016). To some extent, an increased role for private capital goes along with a reduced or altered role of governments within infrastructure investments. In addition, complex instruments and funding flows can make it hard to trace the lines of ownership, or responsibility, affecting governance.

2.1.6.3 Trade

2.1.6.3.1 Goods & Materials Flows

Flows of goods and inputs rise as smaller shares of resource needs are satisfied domestically and separates consumption from production (Lenzen *et al.*, 2012b). Over three decades, the global exports of food have risen 10-fold (UN COMTRADE, 2013). Trade that crosses national borders affects 41% of materials extracted (Robertson & Swinton, 2005; Wiedmann *et al.*, 2015).

Comparing regions, North-East Asia is by far the biggest net importer of raw materials **(Figure 2.1.7)**, with very high net imports of ferrous metals, petroleum and coal per China's enormous demands for these raw materials within industry and infrastructure. The biggest net exporters are Oceania (mainly Australia), Eastern Europe (mainly Russia), South America (mainly Brazil) and Western Asia (mainly Saudi Arabia) – which export based upon immense natural-resources endowments. Australia has large deposits of metal ores and coal, for instance, while for Russia oil and gas reserves have played important economic roles, yielding considerable export revenues.

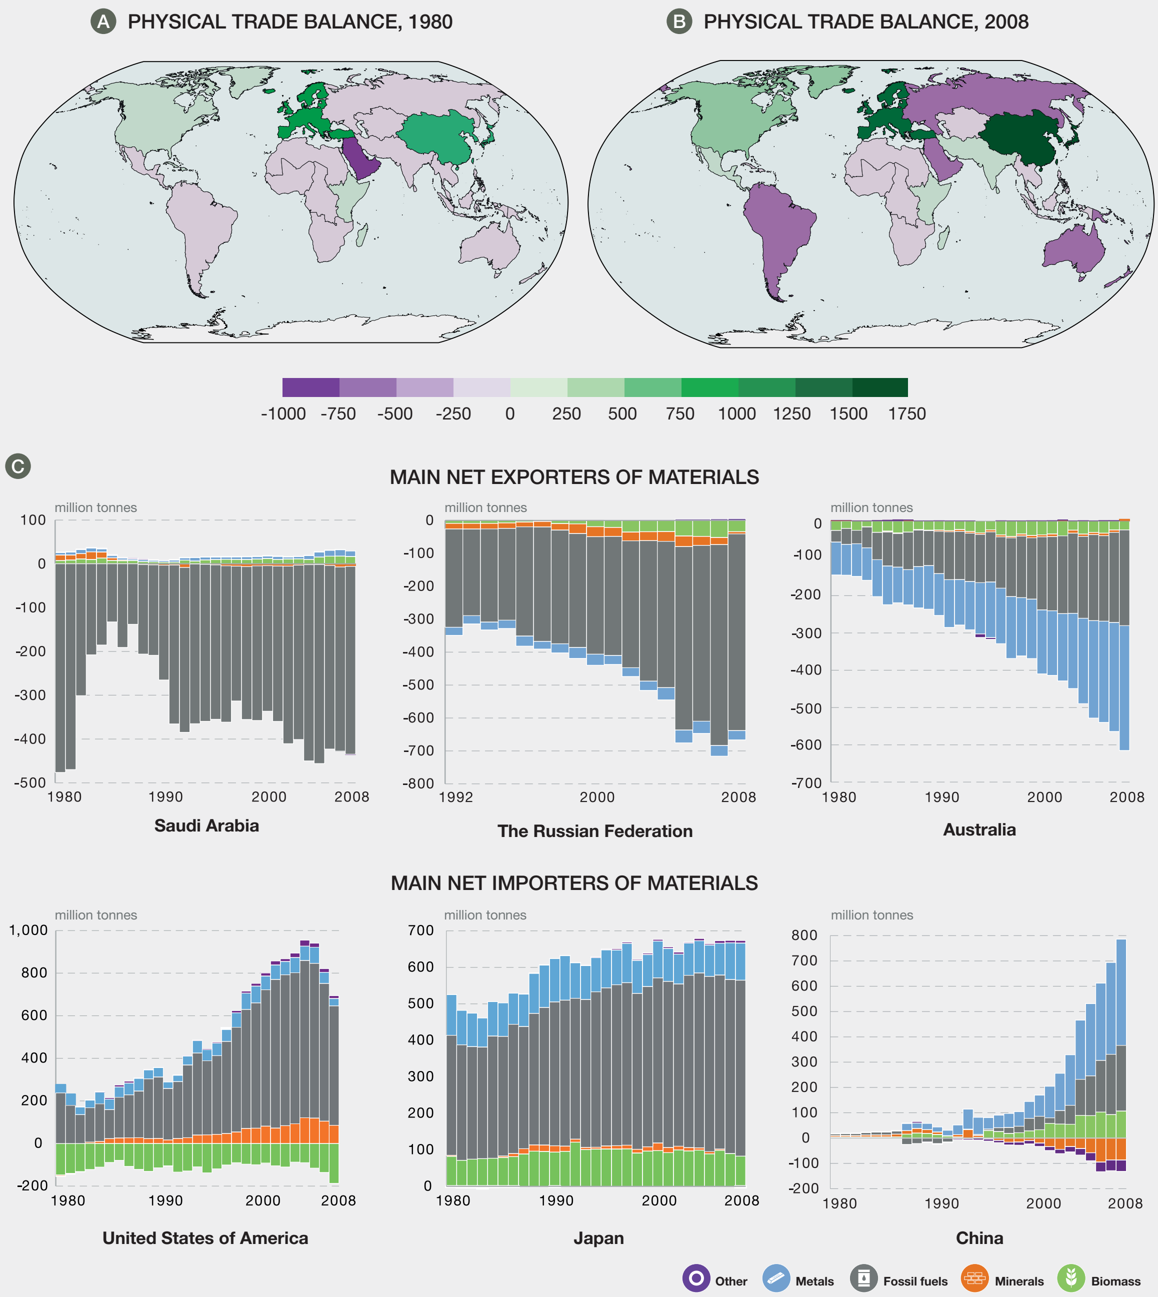

Figure 2 1 7 **The physical dimension of global trade. Physical Trade Balances, by IPBES regions, A in 1980, and B in 2008 (millions of tons).**

The regions in magenta are net exporters of materials, while regions in green are net importers. Underneath are the top three countries in terms of both net imports and net exports, by material categories and physical trade balances. Source: own elaboration with data from WU (2017) (A, B); Dittrich *et al.* (2012) C.

2.1.6.3.2 Telecoupling and Spillovers: trade-offs embedded within the trading of goods

Ecosystems are ever more shaped by distant interactions among countries or 'telecouplings' as the world is becoming more global. Telecouplings refer to socioeconomic and environmental interactions over distances (Sun *et al.*, 2017). Spillovers occur as a result of these telecouplings: effects of (seemingly unrelated) events in one region clearly are experienced in other regions.

The growing trade of goods implies many displaced impacts upon nature – between one quarter and one half of the environmental impacts from consumption are felt in regions other than where the consumption occurs: CO_2 emissions, chemical pollutants, biodiversity loss, and depletion of freshwater resources (IPBES, 2018a). For instance, 30% of threatened species (Lenzen *et al.*, 2012b) and 32% of the consumption of scarce water, i.e., water used within regions with water scarcity (Lenzen *et al.*, 2013), have been linked with international trade. This illustrates spillover effects from consumption of traded goods, in which environmental costs from the production of goods to supply international markets are being incurred far from where the consumption occurs.

Displaced deforestation, pollution, water scarcity, soil loss, and erosion all occur at the expense of ecosystems in other countries, in particular developing countries (Lenzen *et al.*, 2012a, 2013; Moran *et al.*, 2013). Studies considering the impacts on biodiversity. Chaudhary and Kastner (2016) found that 83% of total species loss is due to agriculture for domestic consumption while 17% is due to the production for export. Exports from Indonesia to the USA and China generate high impacts (20 species lost regionally for each). An estimated 485 species currently face high risks of extinction in 174 countries, with about one third of those being a result of current land use patterns **(Figure 2.1.8)**. Perhaps 12% of premature deaths in 2007 from air pollution were caused by pollutants generated by other regions, with 22% arising from the exports of goods and services (Zhang *et al.*, 2017). Exporters get economic returns and technological advancements (Daniels, 1999) but also host negative environmental consequences (Schmitz *et al.*, 2012) – including from monocropping plantations, e.g., for soybean in the Amazon and Chaco, avocados in Central Mexico or cotton, sugar, palm oil and biofuels elsewhere, with health impacts (Lin *et al.*, 2014; Zhao *et al.*, 2015).

It is important to recall that sustainability in one country can rely upon unsustainability in others. Meyfroidt and Lambin (2009) find a 'forest transition' in Vietnam involved displacing extraction elsewhere (Dasgupta *et al.*, 2002; Levinson & Taylor, 2008; Stern, 2004; Suri & Chapman, 1998). In the US, the New England region's forests regrew as railroads linked to the Midwest region that grew in exports due to high agricultural productivity (Pfaff & Walker, 2010). Along those lines, Kull *et al.* (2006), Meyfroidt *et al.* (2010), and Meyfroidt and Lambin (2011) tracked trade to link with forest transitions. Leblois *et al.* (2017) find that countries at the beginning of forest transitions deforest thanks to trade, while those at the end reforest from trade.

Trade redistributes emissions of greenhouse gases **(Figure 2.1.8)**. Production for international markets links with 26% (Peters *et al.*, 2011) to 30% (Kanemoto *et al.*, 2014) of global carbon emissions. However, such effects have been neglected in the relevant international treaties, as carbon accounting was considered solely per country – without including the shifting of emissions from importing to exporting nations (Kanemoto *et al.*, 2014; Peters *et al.*, 2011). These spillovers in fact are larger than reductions in emissions. Thus, relocation of production and degradation affects evaluations of net impacts of governance. Regulations on emissions may appear to be 'effective' in regulated locations, even if degradation simply has shifted to other regions. For instance, since 1990 the UK had measured reductions of up to 16% of domestic CO_2 emissions within its energy and water sectors, yet the CO_2 emissions embodied in imports in those sectors, i.e. those emissions associated to the production of products that are imported, rose 208% in the same time period (Kanemoto *et al.*, 2014).

As to the motivations for such enormous increases over time in the global trade interconnections (and maybe for the lack of interest in tracking them for governance), without a question national scarcities of nature's contributions often have been part of the drive underlying country interests in accessing the nature elsewhere, either directly or embedded in outputs (Figure S11) (Galli *et al.*, 2012; Verones *et al.*, 2017). Exports from the global South, for instance, often have been based on natural assets, including oil and gas (Muradian *et al.*, 2012) that were demanded by countries with growing economies but also growing scarcities of energy. Among the importers of nature, Europe had highest trade flows balances which shifted nature's degradation elsewhere (Dittrich & Bringezu, 2010), yet natural flows are a global phenomenon. In short, as illustrated in **Figure 2.1.8**, exports can have significant costs in local nature degradation.

Turning to potential socioeconomic trade-offs involved, which can vary with implementation as trade can occur on positive or negative terms, the large trade flows sometimes have arisen under contracts with unbalanced sharing of gains (Arduino *et al.*, 2012) and such inequities can get institutionalized in intergovernmental agreements. Merme *et al.* (2014) find different distributions of hydropower benefits in the Mekong Basin under actual contracting than would be expected if all exchanges had occurred under transparent contracting in which all parties were fully informed. Arduino *et al.* (2012) consider how many rentals of valuable lands occurred for low fees, evading Tanzanian laws (and resulting in water pollution). Houdret (2012) connect costly uses of water to the mismanagement of public-private partnerships in Morocco. Transboundary rivers feature conflicts (Biswas, 2011), e.g. a lack of trust between India, Nepal, and Bangladesh over the Mahakali River Treaty despite prior political processes (Khalid, 2010).

In such contexts, some refer to resource exchanges not as 'trade' but as 'grabbing' – in order to explicitly question the adequacy of the levels of compensation involved (Dell'Angelo *et al.*, 2018; Franco *et al.*, 2013). The appropriate label is not always clear. Acquisitions without compensation, such as water diversions or cross-border pollution ("e-waste" in Awasthi *et al.*, 2016), may clearly be 'grabbing'. Yet, adequacy of compensation is "in the eyes of the beholder". Trade can allow all countries to gain from others' strengths, but price is critical for equity – including when the global South imports (potentially displacing production). 'Grabbing' parties may justify transactions by arguing that their investments raise the access to or the productivity of underutilized resources. That possible efficiency rationale for the external inputs does not directly address the distributional consequences for vulnerable local populations.

Nature-economy trade-offs also arise in the conservation of nature in lower-income and least developed countries that effectively exports global public goods, such as carbon storage or species habitat, through forest protection. This may earn global funding transfers, also raising issues of adequate compensation. Overall impacts upon local well-being depend on who gets paid, how much, in which conditions.

Concerning lands, over 1000 deals have been recorded, globally, covering ~50 million hectares. Africa hosts over 400 for ~10 million hectares (Anseeuw *et al.*, 2012; Nolte *et al.*,

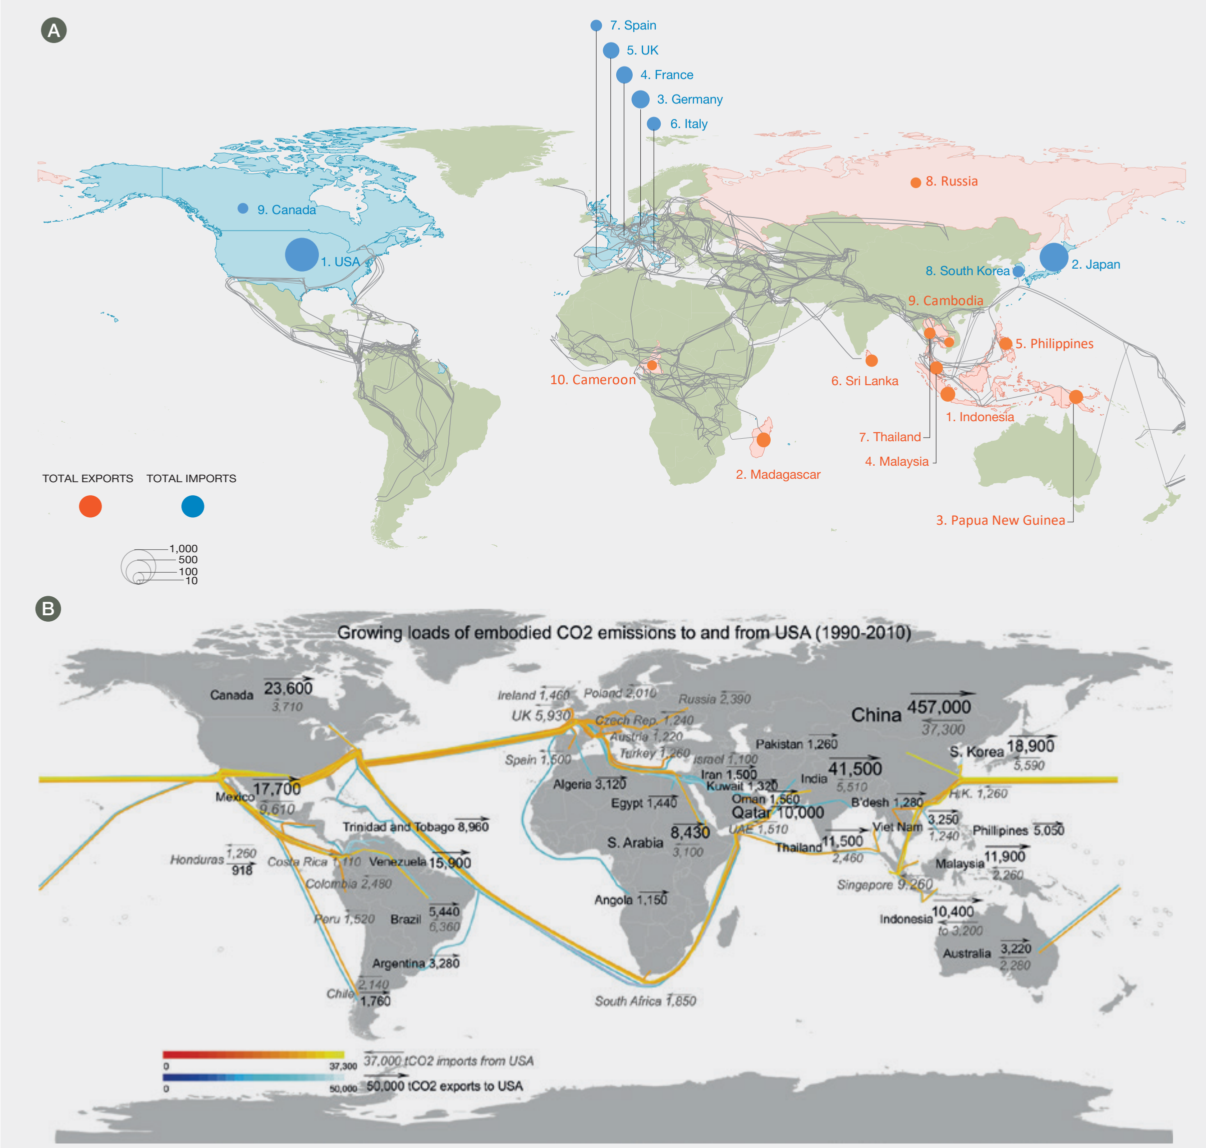

Figure 2 1 8 **Global trade imports and flows measured as biodiversity and CO_2 footprints.**

A Biodiversity footprint showing top ten exporting countries associated with pressures on biodiversity in developing economies and top ten importing countries with respect to pressures on biodiversity (developed and emerging economies); thicker arrows indicate a larger number of threatened species associated with that bilateral trade flow. B Largest growing flows of embodied CO_2 (amount of CO_2 emissions associated to the production of products that are imported to the USA (rightward arrows) and from (leftward arrows), measured as absolute growth 1990-2010 in tons of CO_2). Source: (IPBES, 2018a; Kanemoto *et al.*, 2014; Lenzen *et al.*, 2012a).

2016). Rulli *et al.* (2013) estimate up to 1.75% of cultivable land has been 'grabbed'. Many deals involve conversion of savannah or forest to crops or trees such as oil palm (Borras Jr & Franco, 2012), using water from river basins (Borras Jr *et al.*, 2011). In Africa, investors are largely firms, at times in partnerships with national and local governments. Little evidence exists concerning free, prior, and informed local consent. Instead, weak consultation is reported, yielding protests since customary ownership and custody, with stewardship, coexists with legal state ownership that locally may not be seen as legitimate (Nolte, 2014; Nolte & Väth, 2015). Projected local benefits, e.g., productivity and thus job creation that often is used as justification, have been mixed (Kleemann & Thiele, 2015; Nolte & Väth, 2015). The potential for such conflict must reflect the large shares of global lands held under customary or community-based local regimes (IUCN, 2008), including a significant share held or managed by Indigenous Peoples and Local Communities (see chapter 1) (USAID, 2012).

As to existing plans to address the world's growing agricultural demands, linked also with water, within sub-Saharan Africa, Latin America, Eastern Europe and Central Asia, the lands said to be "available" often also are under formal public ownership and yet used by local groups, including indigenous communities (RRI, 2014). The same issues may arise, then, since regions may suffer implicit "land grabbing" by the consuming countries, via production of agricultural exports which can threaten local food security. The "available" lands also sometimes coincide with areas of high biodiversity. Summing up, if and when lands are converted, justice concerns potentially add to costs in terms of losses of ecosystem services (Sayer *et al.*, 2008).

'Water grabbing' raises all of the same issues as above, again including for agriculture, as noted, and for mining or hydropower generation or often for industry (Merme *et al.*, 2014; Sosa & Zwarteveen, 2012). For the irrigation of cultivable land, demands have been labeled "green" – i.e., extracted by the plants – or "blue" – i.e., pumped (Dell'Angelo *et al.*, 2014; Rulli *et al.*, 2013).

2.1.6.4 Financial Flows

2.1.6.4.1 Remittances

Growing financial remittances after migration, i.e., transfers back to migrants' places of origin, can significantly affect important outcomes for nature within the sending regions. From 1990 to 2015, such remittances rose over 5-fold and were particularly important for poor households in developing countries (e.g., China, India, Philippines, Mexico have the largest absolute inflows of remittances while, as fractions, Tajikistan, Nepal, Moldova and Haiti are high, ranging from one fifth to half of GDP). In 2014, 250 million migrants sent 583 billion US dollars. As the remittances raise disposable income, they can alter consumption patterns in communities. That can, in turn, promote land-cover change due to growth of agricultural activities that need land. In other cases, however, migration yields reductions in subsistence agriculture and, thus, the pressures on lands.

Nine out of the ten most biodiverse countries, globally, are characterized by large- and medium-sized diasporas plus medium to high dependence on remittances. The countries with the largest share of forest lands are not, however, high in migration or dependent upon remittances. Among the top ten countries in the world in terms of highest deforestation rates from 2000 to 2012, only China and the Democratic Republic of Congo have high migration – but even they have low and medium dependence upon remittances. None of those top ten have high remittances per capita.

2.1.6.4.2 Financial Standards

Private investments also are growing and can be very influential. Yet financial returns often do not recognize nature's contributions (World Bank, 2018o). For instance, for sub-Saharan Africa, despite substantial risks of natural depletion, in official assessments total wealth changes are not considered even for large investments. Thus, natural regrowth is not valued, while short-term income from the degradation of nature is counted (World Bank, 2018o).

International institutions can set out environmental and social standards for financial institutions and transactions that borrowers should follow throughout project cycles. Standards can help in doing due diligence to assess risks (EIB, 2014; IFC, 2012; The Equator Principles Association, 2013; World Bank, 2017b). Considering environmental, social and governance (ESG) factors in principles facilitate risk management (Sullivan *et al.*, 2015; van Duuren *et al.*, 2016) that with appropriate counting raises the risk-adjusted, long-term returns from investments (WEF, 2013) and affects assessments of firms' performance (Delmas & Blass, 2010) and financial portfolio (Vörösmarty *et al.*, 2018). By 2016, $23 trillion of assets were managed with 'responsible' strategies that could be of this type – a rise of 25% since 2014 (US SIF Foundation, 2016). Some fund managers aim to track performance with regard to the Sustainable Development Goals, while others track specific social or environmental objectives (Global Impact Investing Network, 2017; GRI *et al.*, 2015; Polasky *et al.*, 2015). Some ideas have been agreed for such guidelines (e.g. The Natural Capital Declaration, GRI Standards for Environmental Reporting; SASB Sustainability Accounting Standards) (GRI *et al.*, 2015; NCFA, 2018; SASB, 2014) but metrics remain a major challenge.

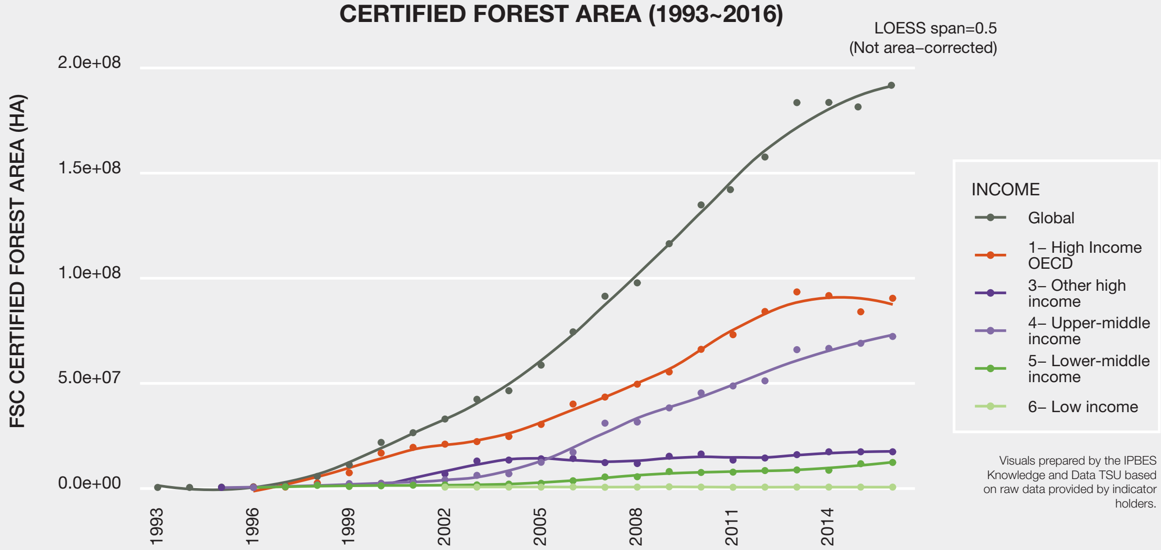
2.1.6.4.3 Tax Havens

The roles of tax havens in the global outcomes for nature are only starting to be documented, given ever larger roles in the global economy. Recent evidence starts to identify possible links between the use of such jurisdictions and the environment (Galaz *et al.*, 2018). Funding via tax havens has been shown to have provided 68% of foreign capital for Amazonian soy and beef production and to have supported 70% of the vessels implicated in illegal, unreported and unregulated fishing.

2.1.7 INDIRECT DRIVERS: GOVERNANCE – MARKET INTERACTIONS

Certification schemes aim to inform supply chain production and consumption. Market-based schemes aim to signal consumers' values to provide incentives for producers to shift processes (Haufler, 2003; Mayer & Gereffi, 2010; Raynolds *et al.*, 2007). Environmental certification exists

A CUMULATIVE SUM OF FOREST STEWARDSHIP COUNCIL (FSC) CERTIFIED FOREST AREA (1993~2016)



B FISHERIES CERTIFIED BY THE MARINE STEWARDSHIP COUNCIL (MSC) (1999~2015)

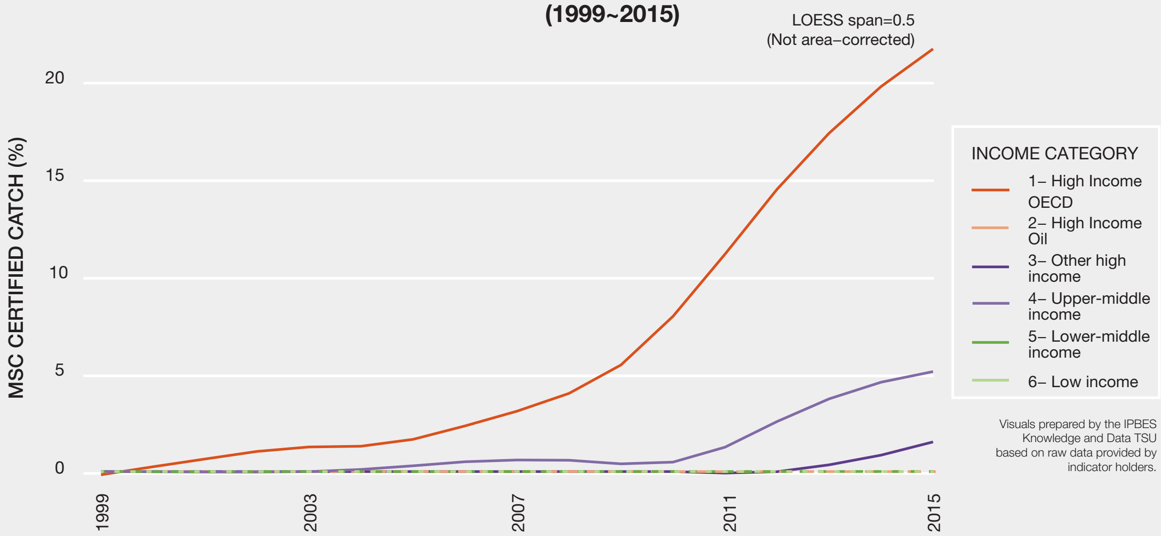


Figure 2 1 9 **Temporal trends in certifications.**

A Cumulative sum of FSC Certified Forest Area (1993~2016); B percentage of fisheries certified by Marine Stewardship Council (1999~2015); this is the sum total of all green weight catch from all certified fisheries, or the weight of landed fish before processing (catch of whales, seals and other aquatic mammals are not included when calculating global catch to compare to MSC fisheries as they are out of scope for MSC certification). Trends show averages from country data, using the World Bank income categories Source: (FSC, 2017).

for a wide range of products – including timber (Klooster, 2005; Molnar *et al.*, 2011) coffee and cocoa (Raynolds *et al.*, 2007; Tscharntke *et al.*, 2015), fish (Constance & Bonanno, 2000), soybean and palm oil (Schouten *et al.*, 2012), nuts and other non-timber forest products (Shanley *et al.*, 2002), horticulture (Hatanaka *et al.*, 2005), floriculture (Hall *et al.*, 2010), biofuels (Selfa *et al.*, 2014) and tourism (Font *et al.*, 2007). Certified area for forests and marine schemes has increased greatly since 2000 **(Figure 2.1.9)**.

Standards dictate the information included within 'labels', which inform actors along the supply chain. They might stimulate a willingness to pay on the part of consumers who value particular practices, as well as firms concerned about their brand reputations as well as political responses (Bartley, 2007; Cashore, 2002; Gereffi *et al.*, 2001; Hatanaka *et al.*, 2005; Potoski & Prakash, 2005). Most of the environmental certifications utilize third-party verification. Thereby, NGOs, scientists and environmentalists design standards and practices alongside industry actors (Cashore *et al.*, 2004; Cheyns, 2011; Gereffi *et al.*, 2001; Hatanaka *et al.*, 2005). Yet, challenges have existed for achieving large impacts, suggesting not only further care in program design and implementation but also a rigorous evaluation of whether impacts arose.

One challenge is that many standards consider production processes, i.e., what the producers did, rather than qualities of outputs that result or specific impacts of the processes such as on nature, creating issues of transparency (Dankers & Liu, 2003). Standards aim to assess things including sustainability, biodiversity, ecosystems, absence of chemical fertilizers and pesticides, quality management, and sociopolitical attributes such as labor and indigenous outcomes (Badgley *et al.*, 2007; Bear & Eden, 2008; Klooster, 2010). Yet, this may present difficulties in measuring the outcomes, or associating them with certification. Many schemes also remain limited in spatial scope. These can make it more difficult to link such schemes with observed differences in, for instance, regional forests and fisheries (Ebeling & Yasué, 2009; Rametsteiner & Simula, 2003).

One additional challenge is to avoid marginalization of smaller producers. Standards developed for large-scale producers or consumer preferences in 'northern' countries may be difficult to apply within small-scale or developing contexts (Foley & McCay, 2014; González & Nigh, 2005). Complex standards may impose requirements that are harder for small-scale producers (Selfa *et al.*, 2014; Tovar *et al.*, 2005), who may not participate in shaping them (Cheyns, 2014; Köhne, 2014; Vandergeest, 2007). There may be costs that smaller-scale and developing country producers with limited capital cannot cover (Clark & Martínez, 2016; Pérez-Ramírez *et al.*, 2012). Their costs may even be higher (Blackman & Rivera, 2011; Lyngbaek *et al.*, 2001; Oosterveer *et al.*, 2014) yet in some cases, they receive political or social support (Quaedvlieg *et al.*, 2014).

Another challenge is to balance rigor and transparency in rule-making process and accessibility (Bush *et al.*, 2013). Legitimacy is often constructed through processes that are open and democratic and incorporate inputs from a variety of actors, including industry stakeholders. That could, however, generate a concern about businesses asserting their interests to the detriment of others (Eden, 2009; Hatanaka *et al.*, 2005; Havice & Iles, 2015; Klooster, 2010). Further, if schemes tend to expand, including in competition among schemes, stringency of such standards could be driven down (McDermott, 2012; Mutersbaugh, 2005; Taylor, 2005). In addition, there may be confusion induced by the presence of multiple such schemes, including industry-led schemes that compete for clients with third-party schemes (Cashore *et al.*, 2007) and can generate situations in which the consumers may not fully understand what each certification label indicates (Bear & Eden, 2008; Yiridoe *et al.*, 2005).

Large-scale public standard setting may then help. For example, the US Lacey Act or the EU's FLEGT (Forest Law Environment, Governance and Trade Mechanism) aim to prevent imports of illegally harvested forest products. FLEGT's Voluntary Partnership Agreements (VPAs) are one effort, that emphasizes independent monitoring, to collaborate with partners in source countries. To improve forest governance, they involve non-state actors such as civil society organizations and the private sector in processes sometimes requiring reconciliation as well as consolidation of conflicting laws (Bollen & Ozinga, 2013). Each VPA includes a system to identify legal products and to license them for import to the EU – with capacity building to help partner countries set up the licensing scheme, enforce, and where necessary reform laws. Legal assurance systems (LAS) are to distinguish illegally produced forest products, with five elements: a definition of legal, in light of producing country laws; a traceability system; a system to verify compliance with the legality definition and traceability system; a licensing scheme; and independent audit capacity.

Guidance for implementation was sought via consultation with major wood-producing countries (Ghana, Cameroon, the Democratic Republic of the Congo, the Central African Forest Commission (COMIFAC), Malaysia, Indonesia and Vietnam) (Hajjar, 2015; Tegegne, 2016) and VPAs have been signed with Ghana, Cameroon, Central African Republic, Republic of Congo, Liberia and Indonesia – while six more countries have been in negotiations (Côte D'Ivoire, the Democratic Republic of the Congo, Gabon, Guyana, Honduras and Laos). Indonesia has done the most such licensing and monitoring, licensing timber and wood-product shipments to the EU and applying standards to shipments to other countries. Some countries that have not yet started such licensing have improved in transparency, while acquiring significant skills, knowledge, and capacities in terms of these FLEGT systems for sharing information, monitoring and traceability of timber.

If rights are not clear, respected, and enforced, certification's outcomes can look very different. Outcomes of the types of certification we considered above appear to depend on effective rights. Forest certification, such as by the Forest Stewardship Council (FSC), considers logging within concessions or communities with effective rights – such as collective *ejido* tenure in Mexico – granted by the state but not always strongly enforced). Studying FSC in Peru, Rico *et al.* (2017) find that where concessions exhibit lower deforestation than surrounding areas, suggesting some effective enforcement, certification had a small positive effect upon forest conditions. However, where concessions had more forest loss than outside, certification has not had significant effect. It also has none within Cameroon (Panlasigui *et al.*, 2018), where PAs do not fare better than outside, suggesting significant limits on forest enforcement. From these examples, it seems that effective rights enforcement complements certifications.

2.1.8 INDIRECT DRIVERS: GOVERNANCE – LOCAL COMMUNITY COORDINATION

Commons or collective property system arrangements are present across the globe in spite of the historical challenges and pressures. Today, they often retain some of their traditional meaning, as part of collective management arrangement of common-pool resources, yet they have responded to various changes. To an extent, awareness of our dependence upon common-pool resources has brought attention to the centrality of property regimes – and their overlaps – for issues including water governance, waste management, congestion, landscape management, and climate change.

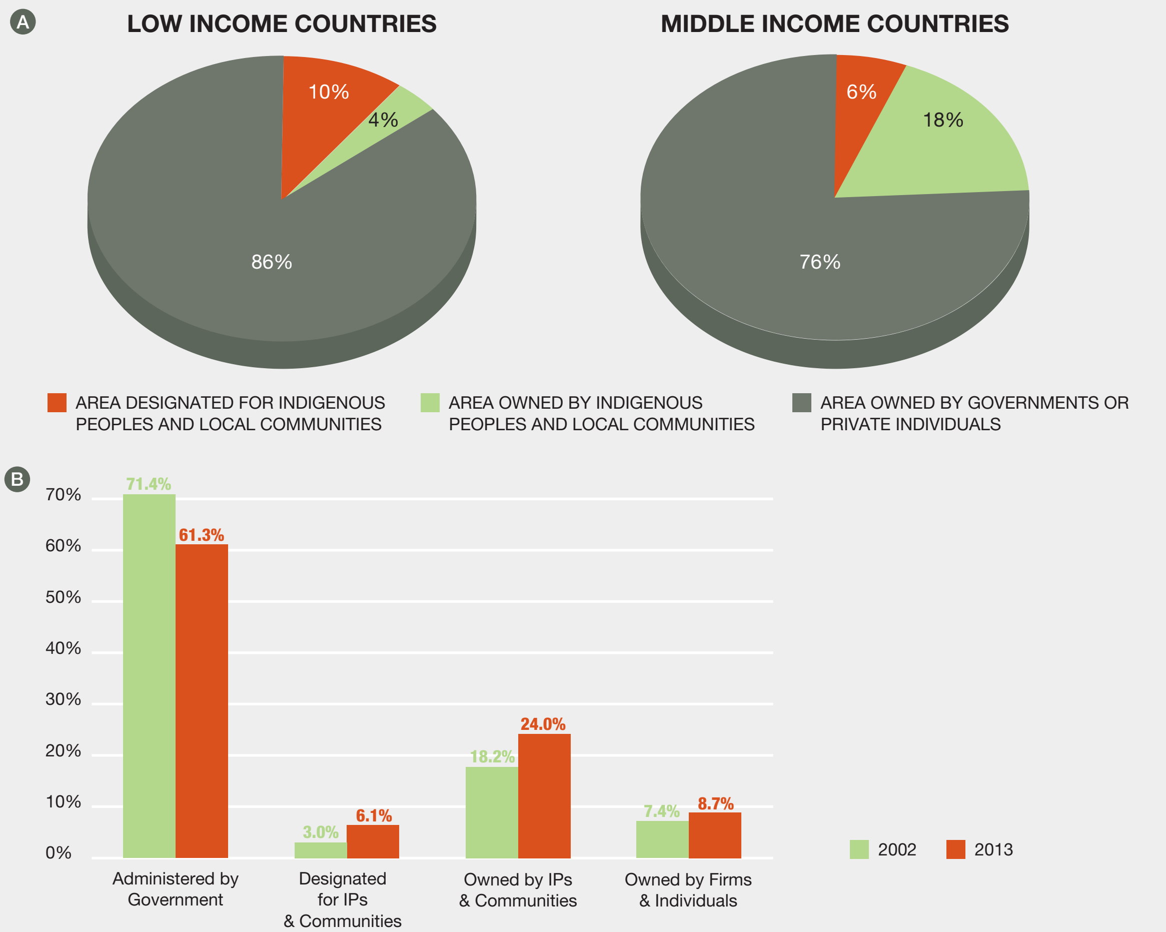

Figure 2 1 10 **"Recent status and temporal change for a number of categories of common land (versus other lands):**

A area under communal tenure regimes for low and middle income countries (including lower-middle and upper-middle income countries), and B % change in statutory forest land tenure in LMICs (low and middle income countries) from 2002 to 2013. Categories shown: area designated for Indigenous Peoples and Local Communities, area owned by Indigenous Peoples and Local Communities and the areas owned by governments or by private firms or individuals. Source: (RRI, 2014).

Historically, and currently in many regions of the world, rural land was owned and governed by local communities – a significant share under varied customary-property-regime arrangements (see chapter 1 for area estimates). State recognition of legal rights applies to only a fraction of the lands (Wall, 2014). Without recognition of legal land rights, many Indigenous Peoples and Local Communities are vulnerable to direct dispossessions and, thus, losses of livelihoods and culture. Customary property systems have often failed to stand up to external pressures related to colonization settlement, expansion of commodity production for agriculture, or forestry, mining, infrastructure extensions, government programs, and conservation programs.

Several international frameworks have tried to address these issues, including the International Labor Organization Convention 169 (ILO, 1989), UN Declaration on the Rights of Indigenous Peoples (UNDRIP), and FAO Voluntary Guidelines on the Responsible Governance of Tenure of Land, Fisheries, and Forests (VGGT) (FAO, 2012b). Also, in many regions communities have gained rights to land resources **(Figure 2.1.10)**, especially within Latin America (Agrawal *et al.*, 2008; Sunderlin *et al.*, 2008; White & Martin, 2002). Across developing countries, it has been estimated that around 27% of the forests are owned or designated for management by local communities, with rights to over 200 million hectares transferred (or just recognized) since 1985. In 2008, globally 24% of forests were owned by communities; 6% owned by governments but used by communities; 9% in private property; and 61% in public hands (Sunderlin *et al.*, 2008).

Securing collective rights and institutions has been considered as a key underlying component in sustained use and management, as communities change with external and internal circumstances (Ostrom, 2000). There are no statistically representative global analyses of effects on nature of community governance, yet there are observations from many case studies: e.g., using data from 80 cases of forest commons across Asia, Africa, and Latin America, Chhatre and Agrawal (2009) associated more local rule-making autonomy with higher carbon storage and livelihood benefits. This can occur because if the sustainability of a locally-relevant common-pool resource system is threatened, local resource users may invest to create new institutions to better local governance.

The recognition that local resource users sometimes craft effective governance has contributed to increased enthusiasm for the devolution of responsibilities to communities for the management of nature (seen within **Figure 2.1.10**). Community-based management after decentralization also can be successful (Amede *et al.*, 2007; Gibson *et al.*, 2005; Kearney *et al.*, 2007; Kellert *et al.*, 2000; Leach *et al.*, 1999; Ribot, 2004; Webb & Shivakoti, 2008) and merits additional understanding too. Further cases of common-pool resources suggest that – without privatization or nationalization – resource users do engage in collective actions to create local institutions to limit inefficient uses of natural resources, including in Indigenous Communities (Acheson, 1988; Baland & Platteau, 1996; Berkes, 1986; McKean, 1986; McKean & Cox, 1982; Ostrom, 1990; Poteete & Ostrom, 2004; Tang, 1992; Undargaa, 2017; Wade, 1988). Motivations for doing so can be clear when locals get direct resource benefits and, thus, are vulnerable to any unsustainable trends (Costanza *et al.*, 1998; Eerkens, 1999; Kelbessa, 2013; Ola-Adams, 1998; Shengji, 1993; Wade, 1988).

Indigenous Peoples and Local Communities have an advantage in designing local institutions, given knowledge of local ecological and social systems (Berkes *et al.*, 1998; Colding & Folke, 2001; Comberti *et al.*, 2015; Gadgil *et al.*, 1993; Nakashima *et al.*, 2012; Ostrom, 1990; Tang, 1994). Furthermore, as locals cross paths more frequently, they can monitor and enforce at lower costs, while also communicating expectations (Berkes, 1986; Ostrom, 1990) and imposing local social costs for violations of agreements. Also, without local participation in the crafting of such rules, constraints may lack legitimacy and credibility and, thereby, be inadequate for conservation (Costanza *et al.*, 1998).

Naturally, past governance institutions have not all been successful, and that reveals the roles of information, values, group size, boundaries, cultural and social homogeneity, and leadership that lowers transaction costs for interactions (Baland & Platteau, 1999; Ostrom, 1990; Wade, 1988). Learning across recent decades highlighted that critical contributions to nature, and livelihoods, have required shared norms, trust, and networks which can be developed through time and effort in reaching agreements (Agrawal, 2001; McKean, 1999; Meinzen-Dick, 2014; Pretty & Smith, 2004; Schlager & Ostrom, 1992). These have been limited by biophysical features, such as size and mobility (Becker & Ostrom, 1995; Schlager *et al.*, 1994), and social features like hierarchical heterogeneity and inequality, unless the well-endowed actors make substantial contributions (Andersson & Agrawal, 2011; Baland & Platteau, 1999; Blomquist, 1988; Dasgupta & Beard, 2007; Olson, 1965). Growing global demands also generate challenges (Agrawal & Yadama, 1997; Chhatre & Agrawal, 2008) with new markets establishing economic relationships lacking prior norms (Berkes *et al.*, 2006; Nietschmann, 1972; Richards, 1997; Smith *et al.*, 2010). For instance, historically, effective local marine regimes were far from market centers (Cinner, 2005; Cinner *et al.*, 2007), yet some institutions have responded to the payoffs from governance to confront even higher external market pressures (Alcorn & Lynch, 1994; Aswani, 1999, 2002; Bauer & Giles, 2002). That included state support of local collective rights which help to hold off commercial interests (Dupar & Badenoch, 2002; Pfaff & Robalino, 2017; Ribot, 2004; Richards, 1997) – while not being a panacea (Hinojosa, 2013).

Contributions to nature and livelihoods depend upon institutional details such as clarity of rights and congruence between such rules and the characteristics of the resource in question. Members of communities have responded better to such voluntary limitations when they have participated in rule design and modification, as well as when monitoring is linked to punishments. Sanctions have been better accepted when matching the seriousness of rule violations, and the context, with mechanisms for resolution of conflicts (Cox *et al.*, 2010). State legitimization of the processes helped (Koppen *et al.*, 2008) – but did not always occur (Bowles & Gintis, 2002; Cudney-Bueno & Basurto, 2009; Sarin, 1993; Utting, 1993; Young, 2001).

Interactions between local and non-local institutions have also mattered, because the ecosystems cross social and ecological scales (Armitage *et al.*, 2007; Berkes, 2008; Brown, 2003; Finkbeiner & Basurto, 2015; Hovik & Reitan, 2004; McKay, 2014). Fisheries provide examples of interactions between states and local institutions, with innovations over time. From the 1960s into the 1980s, small-scale fisheries were seen as failing to realize economic potential and food security (Berkes & Kislalioglu, 1989; Brainerd, 1989; Thompson, 1961), so governance should "rationalize this outdated sector" (Proude, 1973; Rack, 1962) by moving away from the "inefficient traditional practices". That guided aid (Basurto *et al.*, 2017) focused on raising production via improved technologies and infrastructure (World Bank, 2004). By the 1990s, after some notable collapses, over-exploitation became the focus for governance. Lack of rights (Campleman, 1973), mismanagement (Milich, 1999), destructive gear (Christensen, 2018), poverty and overpopulation (Pauly, 1997), urbanization, and globalization all were highlighted, alongside a lack of data. Large-scale offshore industrial catches competed with small fishermen, as well as governance aiming to restrict excess effort plus damaging methods such as trawls that scrape seabeds, longlines that trap seabirds, and non-selective nets that catch fish not consumed and damage protected species (Basurto *et al.*, 2017). This new framing shifted investment towards research on fish stocks (World Bank, 2014) and halted direct lending to fisheries for over a decade, until the World Bank re-entered with lending that was itself focused upon improving organization and governance.

2.1.9 INDIRECT DRIVERS: GOVERNANCE – STATES

2.1.9.1 Adjusting Development Policies

2.1.9.1.1 Property Rights & Resource-Use Rights

Property and resource-use rights, which depend at least in part on the state, affect outcomes for nature in many ways (Fenske, 2011; Platteau, 2000). Such rights arise through both formal and informal institutions, with *de jure* official rights and *de facto* effective rights present in different forms and combinations, and with varied impacts (Arnot *et al.*, 2011; Robinson *et al.*, 2018). Formal titling of land, for instance, is not always sufficient to promote either private investment or conservation (Holland *et al.*, 2017; Sills *et al.*, 2017). Evidence suggests that resource-tenure security is impacted by transport costs, for instance, and thus by distance: remote areas are harder to monitor and, hence, are more open to unsustainable harvesting and illegal invasion and harvesting (Albers & Robinson, 2013; Robinson *et al.*, 2008). Understanding these apparent trends in past impact can guide uses of rights within conservation.

Processes of establishing and defending rights are critical to outcomes for nature and wellbeing. One key process is decentralization, which is ongoing. Decentralization often transfers burdens of enforcing rights to local actors – agencies or users (Larson, 2002; Larson & Soto, 2008) – but sometimes also augments local property and resource-use rights (Coleman & Fleischman, 2012). Like rights in general, decentralization's net impact is specific to (quite variable) contexts, e.g., in Indonesia a recent effort affected forests and livelihoods as a function of many characteristics of communities (Sills *et al.*, 2017). In some settings, collective rights for groups may work better for conservation than do individual rights – although possibly overlapping with them (Baland & Platteau, 1999). Relative impact depends on the fraction of households with use rights, the area and profitability of forest, and species present (Alix-Garcia *et al.*, 2005; Baland & Platteau, 1996; Barsimantov, 2010; Baynes *et al.*, 2015; DiGiano *et al.*, 2013; Griscom *et al.*, 2009). Policy interactions also matter. Other policies such as recent agricultural subsidies and trade policy in Mexico, allowing timber imports from China, undermined domestic forestry profits and responses to collective rights (Ellis, 2014).

2.1.9.1.2 Transportation Investments (by context)

Economic development is influenced by the spatial pattern of roads, which lower transport costs. Globally, transport costs have fallen by ~40% across the last three decades, yielding aggregate economic growth as well as the spatial concentration of economic activity (World Bank, 2009). Highways have raised economic growth (Banerjee *et al.*, 2012; Bird & Straub, 2014; Storeygard, 2016), as well as total employment (Michaels, 2008) and industrial efficiency (Datta, 2012; Ghani *et al.*, 2016) – often, at least in part, through their impacts upon cities.

Some studies have focused upon past rural economic impacts of transport investments. Those are important for trading off with ecological impacts, such as the impacts of roads on forests, which often are higher at forest margins than in highly developed areas (Pfaff *et al.*, 2018). Studies find economic gains in agricultural productivity (Fan & Zhang, 2004; Zhang & Fan, 2004), reduction in poverty, and increased consumption (Asher & Novosad, 2016; Dercon *et al.*, 2009; Gibson & Rozelle, 2003; Khandker *et al.*, 2009) – plus labor shifts from agricultural to non-agricultural sectors (Asher & Novosad, 2016; Gollin & Rogerson, 2010). Another rural impact has been better access to credit and financial services (Binswanger *et al.*, 1993) – though we must allow that road placements often responded to other conditions, so causally identifying impacts can be difficult (Banerjee *et al.*, 2012; van de Walle, 2009). That restricts the quality of impacts evidence (Dulac, 2013; Khandker *et al.*, 2009).

Yet the apparent trends suggest important heterogeneity within economic impacts from transport. Roads have concentrated or dispersed economic activity, depending on the economic conditions. Cities connected to ports, or other cities, often benefitted more from trade and access to markets, as have rural areas along transport corridors, while unconnected rural areas have lost activities (Bird & Straub, 2014; Chandra & Thompson, 2000; Rephann & Isserman, 1994). In addition, labor will concentrate to earn higher wages stemming from economies of scale to human capital (World Bank, 2009). In Brazil, for instance, frontier roads have promoted settlement in many rural areas (Fearnside, 1987) yet, in those regions, urban population growth has been higher than rural rates. In India, given extensively settled rural areas new roads led people into cities (Asher & Novosad, 2016). When considering policy to balance multiple SDGs, the varied trends by context are key.

Transport investments – and in particular roads investments, which differ in impacts from rail – also, have driven large ecosystem losses. Early studies of road impacts mostly considered some economically less developed settings or “frontier” forests (Chomitz & Gray, 1996; Cropper *et al.*, 2001; Nelson & Hellerstein, 1997; Pfaff, 1999). For that broad context, roads expanded the areas where agriculture is profitable, causing further deforestation in the absence of institutional or policy constraints. Such study of deforestation impacts is summarized in reviews (Angelsen & Kaimowitz, 1999; Ferretti-Gallon & Busch, 2014; Geist & Lambin, 2002; Rudel *et al.*, 2009a). Others have summarized trends in how roads affect wildlife and ecosystems (Forman & Alexander, 1998; Laurance *et al.*, 2009). Many authors warn that expected global investments, up to 25 million kilometers by 2050, will surely exacerbate such ecosystem losses (Caro *et al.*, 2014; Laurance *et al.*, 2014, 2015).

Yet the magnitudes and even the signs or directions of transport investments’ impacts varied by: the types of roads; the stage of prior economic development; and economic activities involved (Mertens *et al.*, 2002; Pfaff *et al.*, 2016). While the stories that have dominated the literature and consciousness, including studies of large tracts of undisturbed forest with minimal property rights (Ferretti-Gallon & Busch, 2014; Rudel *et al.*, 2009a), on average suggest potential for high impacts, studies of actual variation in past impacts show that with high prior development, road-induced deforestation is actually lower (Andersen *et al.*, 2002; Pfaff *et al.*, 2007). These trends are suggestive of ways to limit deforestation by confining new transport to existing developed areas (Laurance *et al.*, 2014; Pfaff *et al.*, 2016). In extensively settled, non-frontier areas, for example in India and China, roads investments have even lowered deforestation, if roads encouraged the transition from agricultural to urban sectors (Deng *et al.*, 2011; Kaczan, 2016) and to plantations (Deng *et al.*, 2011; Kaczan, 2016).

2.1.9.1.3 Subsidies to Fuels

Subsidies to fossil fuels have been highly prevalent at least across recent decades, featuring both frequency across space and persistence over time, and all of that in spite of quite enormous costs. The International Monetary Fund states a cost of US$5 trillion – including the externality cost of nature’s degradation – with coal accounting for 52% of post-tax subsidies, petroleum for 33% and natural gas for 10% (Coady *et al.*, 2015). Davis (2016) estimates that there have been US$44 billion just in direct costs from carbon dioxide emissions, alongside traffic congestion, local pollution and also accidents – while noting that the subsidies have greatly reduced relevant actors’ incentives for generating clean innovations. Davis (2014) estimates additional large costs of ‘deadweight loss’ even without any environmental costs.

By all accounts, however, it has been significantly (and persistently) difficult to eliminate these policies that are ‘lose-lose’ in the sense of a worse environment and worse economic efficiency. That seems to be due to enormous public opposition concerning the possibility of their removal, including by affected groups and those advocating on behalf of the poor. However, it was shown that putting into practice a classic adjustment from economics textbooks could actually separate equity concerns from the enormous efficiency losses: cash transfers to the poor can compensate for price rises within any reform to improve key incentives (e.g., Salehi-Isfahani, 2016 on Iran).

2.1.9.2 Increasing Conservation Policies

2.1.9.2.1 Protected Areas and IPLC Lands/Participation

Governments have long created protected areas (PAs) to limit activities imperiling conservation. On the order of 15% of terrestrial and freshwater environments and ~7% of the marine realm are under some form of protection (UNEP-WCMC & IUCN, 2016), making protection the leading strategy to date for conserving biodiversity and ecosystem services. Protected areas were developed to preserve wilderness areas (Ervin *et al.*, 2010; Rodrigues *et al.*, 2004). However, the historically top-down approach to protection has evolved towards more inclusive conservation approaches (Berkes, 2010) – with protection categories ranging from strict (I–IV) to sustainable use (V–VI) (Dudley, 2008). The latter category includes "multiple-use" areas, which sometimes have bottom-up origins (Pfaff & Robalino, 2017). Recent decades saw considerable expansions, globally, in PA numbers and area (UNEP-WCMC & IUCN, 2016). Category VI grew most and it is the largest at ~40% of total PA area, though stricter top-down categories II and IV make up ~27% and ~13% (Juffe-Bignoli *et al.*, 2014), respectively. Also, the distribution of protection is not equal across the regions of the globe. For instance, one quarter of the terrestrial regions and over one half of marine regions are under 5% protected (Butchart *et al.*, 2012; UNEP-WCMC & IUCN, 2016).

Challenges for very significant impacts from PAs, though, arise in both enforcement and siting. Deforestation does occur within PAs, although usually at lower rates relative to the PAs' surroundings, indicating imperfect enforcement (at least for strict PAs), with losses of biodiversity and other services (Coad *et al.*, 2015). Enforcement clearly is critical. Also, it is not always better in strict PAs (Albers, 2010; Ferraro *et al.*, 2013; Fox *et al.*, 2012; Laurance *et al.*, 2012; Nolte *et al.*, 2013). Restrictive marine PAs, which are managed by states, have been effective within countries which have stronger legal frameworks. Bottom-up approaches can require community leadership to succeed, plus support from NGOs and private entities (Jones *et al.*, 2013). They may succeed in part due to lower monitoring costs.

Protected areas have had greater impacts when they effectively limited higher resource pressures. Where pressures are low, PA outcomes may be similar to their surroundings, i.e., impacts can be low and even zero when outcomes are undistinguishable from similar unprotected landscapes (Joppa & Pfaff, 2010; Nelson *et al.*, 2010; Pfaff *et al.*, 2009). One clear reason PAs are in lower-pressure sites is that local actors push back against protection, as they see PAs as a source only of local costs. This is less the case for multiple-use PAs which, depending on locations and enforcement, can have more impact (Nelson & Chomitz, 2011; Pfaff *et al.*, 2014). If PA impacts are higher under pressure, that suggests integration of protection with regional development (Mora & Sale, 2011; Stoll-kleemann *et al.*, 2006), e.g., siting the PAs alongside new roads (Pfaff *et al.*, 2015a, 2015b) and optimizing road siting with impacts on nature and economies in mind (Andam *et al.*, 2010). PAs often imply local cost but also can offer local tourism benefit (Andam *et al.*, 2010; Robalino & Villalobos, 2015).

Indigenous Peoples and Local Communities have long protected, and currently conserve, many ecosystems (see chapter 2.2) and indigenous lands have often had consequential impacts, sometimes more than nearby PAs. Many IPLC approaches to conservation have been scaled up, yet opportunities for participation in global and national policy processes have been limited for IPLCs, although increasing in international organizations such as the CBD. Participation in national biodiversity strategies and action plans (NBSAPs) has been limited to date, with country exceptions. Since 2004, numerous IPLCs have identified concrete actions for adding important principles into national policies and programs for sustainable use of biological diversity (Forest Peoples Programme, 2011), e.g., the Plan of Action on Customary Sustainable Use (adopted in 2014). Many IPLCs are determined to play an active role in implementing this Plan through 2020 and well beyond. For example, a global indigenous coalition from the Amazon, Central America, the Congo Basin and Indonesia pledged to protect 400 million ha of forests (LPAA, 2014) and the Palangka Raya Declaration on Deforestation and Rights of Forest Peoples has concrete policy recommendations to address habitat loss (Forest Peoples Programme, 2014). Amazonian Kayapo people in Brazil are conserving 105,000 km^2 of forests in a frontier characterized by heavy deforestation due to agriculture and pasture expansion, illegal gold miners, logging and infrastructure. They also led (unsuccessful) pressures on the World Bank and other international financing institutions to stop loans for a mega-dam on the Rio Xingu (Zimmerman, 2010). In Kapuas Hulu (West Kalimantan, Indonesia) indigenous Dayak peoples contribute to conserving forest, river and lake habitats that are under threat from oil palm (Colchester *et al.*, 2014; Porter-Bolland *et al.*, 2012).

Given this history, and mixed trends, policymakers and scholars are reconsidering roles of local communities in the context of expansions of both resource use and conservation. Communities' rights have been shown to generate incentives for local protection, monitoring, and enforcement (Berkes *et al.*, 2006). Empowered local fishers have been seen to be more likely to comply with regulations (Bennett & Dearden, 2014). Indigenous and local knowledge, including from women (Agarwal, 2009), has aided conservation success (Brooks *et al.*, 2012; Jones *et al.*, 2013; Stoll-kleemann *et al.*, 2006). Policies that do not undermine local ownership but instead guarantee local involvement in all of design, implementation and benefits (Bennett & Dearden, 2014) have contributed to conservation, as peoples understand their livelihoods depend on maintenance of the environment including via strong organizational and technical capabilities within rural communities (Sim & Hilmi, 1987). Many forests and other biodiverse habitats are within IPLCs' lands and territories (FPP *et al.*, 2016), overlapping areas of high biodiversity and biocultural diversity (Sobrevila, 2008; Toledo, 2013). Yet, there are still limited data about local farmers' and livestock keepers' relations to genetic diversity, in particular for species with cultural or economic values, such as traditional medicines or non-timber forest products (CBD, 2014).

2.1.9.2.2 Payments for Ecosystem Services and Other Incentives

On private lands, payments for ecosystem services (PES) offer compensation for the voluntary acceptance of restrictions to reduce degradation, such as shifts in land uses or polluting practices. PES are conditional on beneficial actions or outcomes. Thus, they generate incentives for voluntary provision of ecosystem services by varied private actors (see also chapters 3 and 6). Payments are made by other private actors (Coase, 1960) or by states, as representatives (Ferraro & Kiss, 2002), based on outcomes like standing forests or related practices (Sattler & Matzdorf, 2013). To date, most PES schemes have used action-based rather than result-based conditionality (Engel *et al.*, 2008; FAO, 2007), if they actually use conditions for payment at all (Ezzine-de-Blas *et al.*, 2016). The payments approach makes sense when the buyers' willingness to pay is above sellers' opportunity costs – else those providers would not supply ES (Nelson *et al.*, 2008; Perrot-Maître, 2006). These payments aim to align private goals with social goals (Dobbs & Pretty, 2008; Muradian *et al.*, 2010). Governments may use them alongside PAs to lower local costs and spillovers, relative to pure mandates alone. For multiple-use PAs, that could even involve providing PES inside PAs – which *de facto* can yield additionality if restrictions alone were being rejected (see Tuanmu *et al.*, 2016 for Wolong in China).

To date, though, PES additional impacts beyond baseline are not so encouraging. PES often have been implemented where opportunity costs are medium to low (Tacconi, 2012), just as for PAs, albeit in this case driven more by private decisions about which lands to volunteer for inclusion. Because information about opportunity costs is private, PES designers face a challenge (Börner *et al.*, 2016; Hejnowicz *et al.*, 2014; Sattler & Matzdorf, 2013), since actors with low profits from clearing forests more frequently volunteer to accept a payment for leaving lands in forest. Thus, payments for standing forest have had limited impacts. Studies suggest low impacts of PES (Robalino & Pfaff, 2013 for Costa Rica). Efficient impact may require targeting. Yet, if a service is a priority, e.g., if drinking water or the electricity from hydropower are scarce (Brouwer *et al.*, 2010), then actors have targeted influential lands upstream of dams or cities and utilized higher payments to overcome competing pressures. When a service such as clean water is an input to a good with economic importance (e.g., soda or beer), again targeting and payment sometimes are higher. Further, some designs could help states to reveal private opportunity cost (Ajayi *et al.*, 2012; Ferraro, 2008; Polasky *et al.*, 2014 using auctions; Sheriff *et al.*, 2009 using observable data) and how resulting surpluses are shared is important, while some authors have shown that not differentiating payments between regions has efficiency losses (Ezzine-de-Blas & Dutilly, 2017; Lewis & Plantinga, 2007; Lewis *et al.*, 2009, for instance consider fragmentation). In China, while 'PES' were perhaps less voluntary, as the state prioritized large areas per flood risks, the compensation appeared to cover local opportunity costs (Uchida *et al.*, 2007). In some settings in Europe and in the US, large PES seemed to align with private sector goals of transitions in production to ecologically friendly systems, yet market actors may want assurance about permanence. Other challenges include the need to target only some participants, without triggering negative fairness reactions (Alpízar & Cárdenas, 2016; Mercado *et al.*, 2017).

One way to raise the incentives for ecosystem services suppliers is to allow multiple ecosystem services to be sold on the basis of a single shift in land use. In Bolivia, for instance, *Acuerdos Reciprocos por El Agua* yielded both water and biodiversity outcomes (Wunder & Albán, 2008). Payment for one service does not, then, offer the socially efficient 'price' to align the incentives. Private actors should face incentives based on all of the ecosystem-service gains due to their acts. Thus 'stacking', or suppliers receiving a separate payment for each service, can be more socially efficient for PES programs – although not for all regulatory structures (Pfaff & Robalino, 2017).

Another challenge has been uncertainties, given variations in species or other ecosystem-service benefits across locations. Planners may wish to target an ecosystem service, yet monitoring could involve high costs. Hily & Gégout (2016) study PES designs with unobserved costs and benefits which could be considered for biodiversity conservation policy – alongside PAs plus regulations like the Natura 2000 (N2K) policy that covers 18% of the EU's terrestrial surface (or, generally, "command-and-control" like the EU's Habitats Directive and the US Endangered Species Act). Incentives-based contracts for biodiversity conservation in forests have been implemented in EU states including Denmark, Germany and Slovakia (Anthon *et al.*, 2010; Ecochard *et al.*, 2017). Hanley *et al.* (2012) and de Vries and Hanley (2016) review studies of incentives for biodiversity with varied costs and benefits from conservation, hidden information (asymmetric across actors such as their private costs), and stochastic elements as well (Armsworth *et al.*, 2012). Targeting based on costs and benefits has been suggested (Babcock *et al.*, 1997; Duke *et al.*, 2013; Naidoo *et al.*, 2006). Experiences have showed that an understanding that allows planning around such heterogeneity allows gains (Bamière *et al.*, 2013, for example, compare an auction to a uniform subsidy in order to reach a specific configuration of lands). Auctions have been investigated (Fooks *et al.*, 2015; Schilizzi & Latacz-Lohmann, 2007) that consider not only costs but also benefit-cost ratios (Che, 1993; Latacz-Lohmann & der Hamsvoort, 1997). The efficiency from targeted auctions depends on the relative variability of costs and benefits, as well as their correlation (Ferraro, 2003), however, and any implementation assumes states have accurate knowledge, which may not hold for biodiversity.

For this domain, once again policies have considered collectives, or groups, attempting to apply lessons from common property settings, as 27% of forests in developing countries are under collective title and this percentage may increase with devolution (Agrawal *et al.*, 2008; Molnar *et al.*, 2011). Private rights and state enforcement have not always succeeded (Dietz *et al.*, 2003). Positive group examples exist for: forests (Pagdee *et al.*, 2006); irrigation infrastructure (Wade, 1985); fisheries (Acheson, 1988; Feeney *et al.*, 1990); and pasture (Moritz *et al.*, 2013). Communication and trust are key elements (Hackett *et al.*, 1994; Ostrom, 2000; Pretty, 2003). Inequality hinders collaboration and participation, yet gains are lower for the socioeconomically disadvantaged (Agrawal & Gupta, 2005; Kumar, 2002). In PES for collective titles and decision making (Hayes *et al.*, 2017; Kerr *et al.*, 2014), i.e., when contracting with groups of relevant landholders, responsibilities and rewards are collective and communities motivate members using internal governance to address challenges such as free-riding. A limited literature suggests collective PES could help in rule setting (Hayes *et al.*, 2015, 2017), attitudes towards rules (Sommerville *et al.*, 2010), and, ultimately, sustainable resource use (Clements *et al.*, 2010) – especially when local actors are involved in the designs of programs (Cavalcanti *et al.*, 2010; Kaczan *et al.*, 2017; Walker *et al.*, 2000).

Pre-existing collective arrangements have been important in PES, leveraging members' existing collective motivations (Muradian, 2013; Muradian *et al.*, 2010; Porras *et al.*, 2008), and facilitating the coordination with intermediaries (Jack *et al.*, 2008). Collective contracts can help due to lower per-participant costs, given economies of scale in monitoring (Kaczan *et al.*, 2017) and lower transactions costs with fewer large contracts (Kerr *et al.*, 2014). Also, in terms of ecosystem-service benefits, contracts which cover larger areas can of habitat can match needs of species (Swallow & Meinzen-Dick, 2009).

Collective contracting could face a challenge when sanctions are required to enforce compliance, as has become apparent for "non-point" emissions, where emissions cannot be linked to people due to monitoring costs. While schemes exist if only aggregate pollution is measured (Alpízar *et al.*, 2004; Cason & Gangadharan, 2013; Cochard *et al.*, 2005; Poe *et al.*, 2004; Segerson, 1988; Spraggon, 2002, 2004; Vossler *et al.*, 2007; Xepapadeas, 1991) in practice they are not adopted – partially due to a lack of fairness, as people are punished for others' acts. Yet such an approach can work with strong collective function (Kaczan *et al.*, 2017).

2.1.9.2.3 Choosing Policy Instruments

Many instruments have been used to either support or regulate activities that affect nature, both incentives and restrictions. For instance, current policy debates consider a carbon tax (a "price") which does not dictate a specific process or technology, as well as restrictions on level of output. When quantities have been restricted, sometimes "cap-and-trade" regulations have started with a limit – e.g., on total fish extracted or total emissions – that is broken up into individual limits, which individual actors are allowed to trade flexibly among each other. Firms that innovate need fewer emissions permits and, thus, could sell permits to other firms – creating an incentive to innovate.

While the implementation of these kinds of policies has often assumed 'perfect information', a fundamental challenge arises with various types of uncertainty and other deficient information. Weitzman (1974) considered uncertainty in regulations' costs and benefits, finding that the best policies considered relative sensitivity of the costs and the benefits. A cap policy allowed costs to vary, while a price policy (via a tax) allows amounts, e.g., emissions to vary. Thus, when the benefits of regulations are very sensitive at a threshold, it has been deemed better to be sure of quantities through caps (using trading for cost flexibility). However, if regulations' costs were sensitive, as is the economy, it has been deemed better to keep a handle on the costs, by using taxes. This has all been applied for different uncertainties (Fishelson, 1976; Stranlund & Ben-Haim, 2008; Yohe, 1978) and non-linearities in costs and benefits (Kelly, 2005; Yohe, 1978).

2.1.9.3 Equity Considerations

2.1.9.3.1 Wealth-based and Race-based Differences

Equity is an important, yet complex aspect of policy related to economic development and nature. For regulations like emissions limits, with permits trading for efficiency, distributional outcomes have varied greatly (Bento, 2013; OECD, 2006). For instance, regulations may unequally burden low income laborers – who face additional effects if firms shift into capital (Fullerton & Heutel, 2007; Fullerton & Monti, 2013), or employment shifts sectors (Bento, 2013), such as in the US post-1970s due to the Clean Air Act (Greenstone, 2002; Walker, 2013). Political implications of policy costs draw increasing attention (Bento, 2013; Bento *et al.*, 2005; Fullerton, 2011; Kolstad, 2014; Parry *et al.*, 2006; Pizer & Sexton, 2017). Looking ahead, based upon past efforts, policy revenues from pollution taxes or auctions of permits may invested in reducing other taxes (Bento & Jacobsen, 2007; Dinan, 2012; Metcalf, 1999, 2008; Parry, 1995; "revenue recycling" in Poterba, 1991b) or in tax credits or specific programs for lower-income households.

In evaluating equity implications of the environment policies put into place during past decades, challenges remain for calculating benefits and costs. First, willingness to pay by citizens is hard to know, although the lower-income households seem less willing to pay due to limited income. Second, heterogeneous behavioural responses generated heterogeneous impact from policies, e.g., changes in exposure risks, even if policy was "provided equally" (Bento, 2013; OECD, 2006).

Trade-offs based on heterogeneities across actors also arise when a few small producers are more efficient, putting efficiency and equity in tension (Birkenbach *et al.*, 2017; Brandt, 2005; Brinson & Thunberg, 2016; Da-Rocha & Sempere, 2017; Grafton *et al.*, 2000; Homans & Wilen, 2005; Olson, 2011). Transferable fishing quotas (ITQ) have offered examples, as efficiency may be high if a fleet has fewer vessels – avoiding 'overcapitalization' – yet that favours large industrial producers over artisans. Small-scale

Box 2 1 3 United States, examples of inequalities in exposures to environmental quality.

Scholars have illustrated equity issues concerning, for example, chemical facilities' toxic emissions (Ash & Fetter, 2004; Mohai *et al.*, 2009) and cumulative health risks from multiple pollutants (Morello-Frosch & Shenassa, 2006; Morello-Frosch *et al.*, 2011; Sadd *et al.*, 2011; Su *et al.*, 2009), as well as for environmental amenities, such as grocery stores and more healthful foods (Hilmers *et al.*, 2012; Morland *et al.*, 2002), parks (Boone *et al.*, 2009; Sister *et al.*, 2010), and overall tree cover (Heynen *et al.*, 2006; Landry & Chakraborty, 2009; Schwarz *et al.*, 2015).

There are debates over how best to document disparities, for risks and amenities (Chakraborty *et al.*, 2011; Mohai *et al.*, 2009; Mohai & Saha, 2006), yet race- and income- and wealth-based disparities appear to have persisted in varied forms. Crowder & Downey (2010) found that, at neighborhood level, black and Latino households were more likely to experience high levels of proximate industrial pollution – and across levels of income. Varied case studies document communities' struggles against lead smelters (Bullard, 2000), toxic chemical facilities (Purifoy, 2013), concentrated animal feed operations (Wing *et al.*, 2000), oil refineries (Lerner & Bullard, 2006) and cumulative impacts from multiple polluters (Sze, 2007).

As exposures are based on location, this raises locational segregations by race as well as wealth and, thereby, the legacy of racially-based housing (Katznelson, 2005; Lipsitz, 2006; Satter, 2009) and residential policies based on house type and lot size (Meyers, 2003; Nelson, 1996). As race corresponds with wealth, segregation is apparent, including as per discriminatory residential steering practices within real-estate (Bullard *et al.*, 2007; Ford, 1994). Some degree of immobility is central within exposure inequity, with race and wealth limiting options (Aiken, 1985; Jepson, 2012; Mills, 1997), since wealth disparities are a self-reinforcing feature that limits the mobility of minorities (Bullard, 2007; Darity *et al.*, 2006; Oliver & Shapiro, 2006). Poorer families might well, then, make rational choices to face higher pollution, so as to lower their costs, given lower incomes. Further, adding resource amenities or reducing environmental dis-amenities, which yields higher rents, could help local owners but hurt renters.

Unequal exposures over space and groups can be due to public choices, for instance in the US for communities struggling against hazardous waste incinerators and dumpsites (Bullard, 2000; Cole & Foster, 2001) and solid waste facilities (Pellow, 2004). Public zoning choices interact with immobility if the dis-amenities drive out those who can afford to move (Silver, 2007; Taylor, 2014), although political inclusion in environmental decisions is a core plank of environmental justice – indeed the definition of environmental justice for the USA Environmental Protection Agency (EPA) is: "fair treatment and meaningful involvement of all people, regardless of race, color, national origin, or income, with respect to the development, implementation, and enforcement of environmental laws, regulations, and policies" (US Environmental Protection Agency, 2016, 2018). However, in considering the past trends in placements of dis-amenities, the EPA failed to issue a single finding of racial discrimination in the permitting of hazardous facilities under the Civil Rights Act (US Environmental Protection Agency, 2016). Thus, even explicit statements do not guarantee political inclusion.

Post the Civil-Rights-era, policies also advance "color-blind racism" (Bonilla-Silva, 2010) using seemingly race-neutral terms such as 'multifamily' or 'subsidized' (Morris, 1997). A California report suggests those least likely to resist waste-to-energy facilities: low income; high school or less education; and open to promises of economic benefits (Cerrell Associates & Powell, 1984). This maintains disparities (Bonilla-Silva, 2010). It seems such inequities may be shaped by broader mechanisms, e.g., those underlying mass incarcerations (Agnew, 2016; Brown *et al.*, 2016; Gilmore, 2007; McKittrick & Woods, 2007; Pellow, 2016; Woods, 1998).

fishers or vessel owners may simply sell and exit, lowering welfare in lower-income communities (Carothers *et al.*, 2010; Olson, 2011; Stewart & Walshe, 2008). Fewer vessels could also lower employment, although extended fishing seasons could increase the total hours worked, increasing the overall wage bill. Consolidation of production within a few larger firms also impacts many shore-side firms as well as employment within the processing sector (Abbott *et al.*, 2010; Anderson *et al.*, 2011; Birkenbach *et al.*, 2017; Brandt, 2005; Copes & Charles, 2004; Olson, 2011). To address this, states have in some cases restricted the transfers of fish permits, reducing efficiency gain (Da-Rocha & Sempere, 2017; Grafton *et al.*, 2000; Kroetz *et al.*, 2015).

Moving to environmental quality and exposures, some example of outcomes have illustrated the issue of unequal distributions of environmental burden, one present in many parts of the world.

2.1.9.3.2 Policy Responses (rights, subsidies)

In fisheries and forests, public restrictions on extraction have been shown to have the capacity to help efficiently trade-off nature and individuals' basic needs. Extending to individual actors can further increase efficiency and address equity too. A lack of agreed rights and restrictions in, e.g., open-access fisheries, have been showed to be responsible for dissipation of economic rents and degradation of stocks (Caddy & Cochrane, 2001; Charles, 1988; Gordon, 1954; Kronbak, 2014). On a global scale, those fisheries harvested by multiple countries are more likely to be degraded (McWhinnie, 2009), while exclusive economic zones to exclude foreign fishers are a response. Economic costs of misaligned incentives are over $80 billion annually (Kelleher *et al.*, 2009), including from misallocations of labor and capital (Homans & Wilen, 2005; Kelleher *et al.*, 2009; Manning *et al.*, 2018; McElroy, 1991; Pauly *et al.*, 2002). Restricting effort or gear lowers inefficiencies – but all individuals must be limited or rents get dissipated and inequity arises (Homans & Wilen, 1997; Wilen, 2006). If regulators close access after a fixed total harvest, instead of fixing individual rights, then fishers will race (Birkenbach *et al.*, 2017) with costs (Grafton, 1996; Huang & Smith, 2014) and risks (Pfeiffer & Gratz, 2016).

Individual fishing quotas (IFQs) or catch shares reduced costs of racing by offering more secure shares of total allowable catch (TAC). Catch-share systems have grown since the 1970s (Christy, 1973) in part because exclusive economic zones made it possible for regulators to restrict access (Costello *et al.*, 2010; Tveteras *et al.*, 2011). Shares give fishers a stake in the health of a fishery and may lower collapse (Costello *et al.*, 2008; Essington *et al.*, 2012; Melnychuk *et al.*, 2012). For a non-mobile fish species, one variant is "Territorial Use Rights for Fisheries" (TURFs), which give a specific harvester exclusive access to an area (Wilen *et al.*, 2012). Incentives issues and fairness issues still arise (Abbott *et al.*, 2010; Bromley, 2009; Grimm *et al.*, 2012; Kristofersson & Rickertsen, 2009). Some may be addressed by property rights for collectives, as found in small-scale fisheries (Acheson, 1988; Basurto *et al.*, 2012; Feeney *et al.*, 1990; Leal, 1998), which produce half of the total global fish harvest (Jacquet & Pauly, 2008). One way or another, though, all such decisions about rights allocations have equity implications.

Another response to marine equity issues is subsidies, raising equity and efficiency issues just as for fossil fuels (CWN'18/10). *The Sunken Billions* (FAO, 2009c) has estimated total global rents from marine fisheries and found that overfishing lost US$51 billion in rents in 2004 (supported by Sumaila *et al.*, 2012). An update found losses of US$83 billion in 2012 (World Bank, 2017a) These figures suggest that in some areas rents were negative, i.e., revenues did not cover costs, necessitating subsidies for firms to continue (World Bank, 2018o). Despite data limitations, such results clearly suggest widespread overfishing and declining fish stocks, i.e., huge inefficiencies likely to involve and lead to inequities if limitations are then extended.

Any limitation on communities' extraction rights is a significant equity concern for the IPLCs, including in the context of trade that responds to national differences in the rights for resources (Chichilnisky, 1994; Krausmann *et al.*, 2009). Affluent 'Global North' industrialized countries import from resource-rich countries in the 'Global South', where stocks have fallen (Garmendia *et al.*, 2016)but states often capture little surplus. Martínez-Alier (2002) notes 'ecological debt' to the South, referencing varied inequalities over time within such exchanges relevant for nature (while here we focus upon the rights issues underlying inequities, this links to 'grabbing' above).

Indigenous Peoples, in particular, have highlighted threats from petroleum and mining activities, which were authorized and incentivized by national governments, as in Ecuador (Forest Peoples Programme, 2007). Mining's threats to the food security of Indigenous Peoples were seen in the Philippines (Working Group on Mining in the Philippines, 2009). Violent confrontations have occurred, e.g., an incident occurred in 2009 in Peru after a lack of consent by Indigenous Peoples for petroleum firms to enter indigenous territories. Indigenous Peoples in Latin America, Asia, and Africa are not categorically opposed to mining – although they struggle to hold companies and governments accountable for the negative local impacts (Herbertson *et al.*, 2009; Richardson, 2007). Water contamination from mining, for instance, continues to stir up such heated conflicts (Anaya, 2011; Van de Wauw *et al.*, 2010; van der Sandt, 2009). In the Philippines alone, by one account, there were 800 extrajudicial killings. in the period 2001–

2006, associated with protests against mining (Doyle *et al.*, 2007).

2.1.9.3.3 Equity & Environmental/Energy Taxes (context dependence)

Equity impacts of taxes have varied across contexts, including by the type of commodity plus the physical, social and climatic characteristics. Relevant characteristics have included the transport infrastructure, housing stock, diffusion of technology, incomes, and patterns of work (Cronin *et al.*, 2017; Pizer & Sexton, 2017). In the UK, the share of households' budgets spent on natural gas falls with household total expenditure, since gas is used for heating. In this case, natural gas taxes are regressive, i.e., their burden falls more heavily on the poor. Yet, the budget shares for natural gas rise with household expenditure in Mexico – where there is less need for heating overall and less adoption of home-heating capital at lower incomes. Comparing the UK to the US, which has more similar incomes, due to climate the UK does less cooling – whereas air conditioning uses significant electricity in the US (less in coastal areas which also exhibit higher incomes). Mexico is warmer but its electricity budget shares are lower, with low air conditioning (Davis, 2014). In general, equity impacts depend upon use. Another example is the gasoline tax – which is progressive or neutral in the UK, yet regressive in the US because of more use by the poor with less use of public transit plus longer commutes.

Electricity taxes' direct effects have been regressive, for most settings, reflecting the importance of electricity. Much as for food and water, the expenditure shares decline with the income level. US households with lowest expenditures devote nearly 7% of their total spending to electricity, over three times the budget share for the wealthiest decile (Pizer & Sexton, 2017). In the UK, electricity budget shares decline from over 8% among the poorest households to barely 1% for the wealthiest. Likewise in Mexico, to a lesser degree (Pizer & Sexton, 2017). Flues & Thomas (2015) find electricity taxes to be regressive in 21 OECD countries based on expenditure shares.

Yet, energy and gasoline taxes tend not to be regressive in poorer countries, as vehicle ownership rates as well as commuting patterns matter greatly. Transportation-fuels taxes are thought to be progressive in Brazil, China, Costa Rica, Mexico, and Turkey, as well as in Chile and Hungary, where vehicle ownership differs across incomes by an order of magnitude (Flues & Thomas, 2015; Pizer & Sexton, 2017). In Ethiopia, modern transportation in any form is beyond the reach of the poorest households and, thus, a transportation-fuels tax is strongly progressive (Flues & Thomas, 2015; Sterner, 2012). Indirect effects of taxes, however, still sometimes have been regressive. For instance, diesel taxes raise the cost of public transport, which impacts the expenditures of low income people (Flues & Thomas, 2015; Pizer & Sexton, 2017). Yet overall, low income households have been less affected by the indirect impacts of energy taxes because they consume less (Hannon *et al.*, 1978; Herendeen *et al.*, 1981). Mass transit systems lower private vehicle use in Europe, where longer commutes in one's own vehicle are rare (Haghshenas & Vaziri, 2012; Stutzer & Frey, 2008). In contrast, in the US, lower-income people are likely to own automobiles and drive relatively long distances (Pizer & Sexton, 2017). Gasoline taxes even have had significant effects on economic growth (Hamilton, 2009; Kilian, 2008a, 2008b) – plus upon housing markets (Sexton *et al.*, 2012), in terms of both home construction (Molloy & Shan, 2013) and home price (Morris & Neill, 2014).

Finally, in terms of how such issues arise in official measurements, perceived regressivity falls if considering groups in terms of their consumption instead of expenditures, which fluctuate less – most likely as they track expected lifetime income (Poterba, 1991a). How one ranks households matters so much that: if calculating using income, fuel taxes in Germany and Sweden have been regressive; while using expenditures, it is the opposite. A challenge for addressing equity issues, then, is that expenditures can vary considerably across households which have the same income.

2.1.10 INDIRECT DRIVERS: GOVERNANCE – GLOBAL COORDINATION

"Global commons" often refers, loosely, to resources domains in which many countries interact, indicating shared natural resources such as the oceans, the atmosphere, outer space and the polar regions. According to the World Conservation Strategy (IUCN, 1980), in this common form of usage: "global commons includes those parts of the Earth's beyond national jurisdictions … the open ocean and the biodiversity it contains … or [parts] held in common, as the atmosphere and the Antarctica".

Global commons clearly merit attention, including specifically those domains with common-pool resources, which are rivalrous – i.e., one consumes at the expense of others – and for which it is costly to exclude potential users, e.g., when a resource is large and abundant, plus resource users are disconnected from each other. A leading challenge is the design of governance structures and management systems capable of addressing multiple public and private interests given resources with those characteristics. Mutually agreed mutual coercion is called for to avoid 'tragedy of the commons' at any level (Hardin, 1968; Ostrom, 1990).

Conditions can make global collective management easier or harder. For instance, resource scale, number of users, absence of a shared culture for resource users, and more heterogeneity globally than for local management of common-pool resources (Dietz *et al.*, 2003) all matter. Social learning about the resource dynamics and the implications of diverse uses is critical too.

Various global environmental protocols were deployed in the last 50 years, especially after the 1972 Stockholm Intergovernmental Conference. The Montreal Protocol to address the 'ozone hole', for instance, has become a reference for linking governments and the private sector and contributing to promote economic, technological, and behavioural changes. On the other hand, many legally binding protocols do not provide a full solution for global commons governance, since they are slow to be implemented, or lack either monitoring or enforcement capacity and activities. Patterns of adoption over time can be seen within **Figure 2.1.11**, by country income levels (also see Figure S16).

Some cooperation has involved aquatic ecosystems, including wetlands that reduce impacts of floods, coastal storms and high temperatures as an alternative to 'grey' or engineered solutions. Loss of wetlands to food production reduces flood protection and storm-water management, a tradeoff. Yet, nonetheless, one third of global mangrove ecosystems are depleted or severely degraded. In India, Philippines, Vietnam and the Americas they have been extensively cleared and overall the world has lost 50% of wetlands since 1900. Davidson (2014) review 189 reports of changes in wetlands, reporting average long-term losses of natural wetlands near 50%, since 1700, and as high as 87% – with rates of loss more than three times faster for inland wetlands. Facing such pressures, the Ramsar Convention on Wetlands of International Importance is one intergovernmental mechanism concerning wetlands protection globally. To date 169 countries participate, having designated over 2,200 wetlands of international importance (Ramsar Sites) which together cover an area of 215 million hectares, an area that is equivalent to the size of Mexico. Yet it remains uncertain whether these commitments by national governments to the Ramsar Convention have actually had impacts in significantly reducing rates of wetlands loss.

Other global agreements also concern water management, e.g., the Boundary Waters Treaty of 1909 set up mechanisms to resolve disputes over waters between the US and Canada, while the Helsinki Rules on Uses of the Waters of International Rivers of 1966 include recommendations for regulations when rivers and connected groundwater systems flow across national boundaries. Approved and adopted by International Law Association (ILA), this still lacks any enforcement.

Among 'global' coordination actions, we consider regional social systems and ecosystems, especially if they cross international boundaries. One example is the Johnston Agreement of 1955 concerning Israel, the West Bank, the Gaza Strip and Jordan, with conflict-resolution mechanisms regarding water scarcity. The Indus Waters Treaty of 1960 addresses water distribution between Pakistan and India. Regulatory authority for three "eastern" rivers (Beas, Ravi, Sutlej) was given to India, with the authority for three "western" rivers (Indus, Chenab and Jhelum) given to Pakistan and mechanisms for water sharing sketched out for sectors such as irrigation, transport and power generation. One global effort has been the Convention on the Protection and Use of Transboundary Watercourses and International Lakes – Water Convention – due to the United Nations Economic Commission for Europe. This entered into force in 1996, with 40 states and the European Union as parties and mandates to: improve states' efforts to shield and organize shared water systems and groundwater; and promote cooperation with joint decisions including governance with monitoring, research, consultations, warning systems and knowledge exchange.

Moving to the oceans, recognition of the International Council for the Exploration of the Sea as an expert body for the governance of marine resources occurred in 1928, while in 1945 the FAO was founded to identify and address key challenges to revitalizing the fisheries sector in Europe. Challenges were over-fishing and over-capacity. Regional

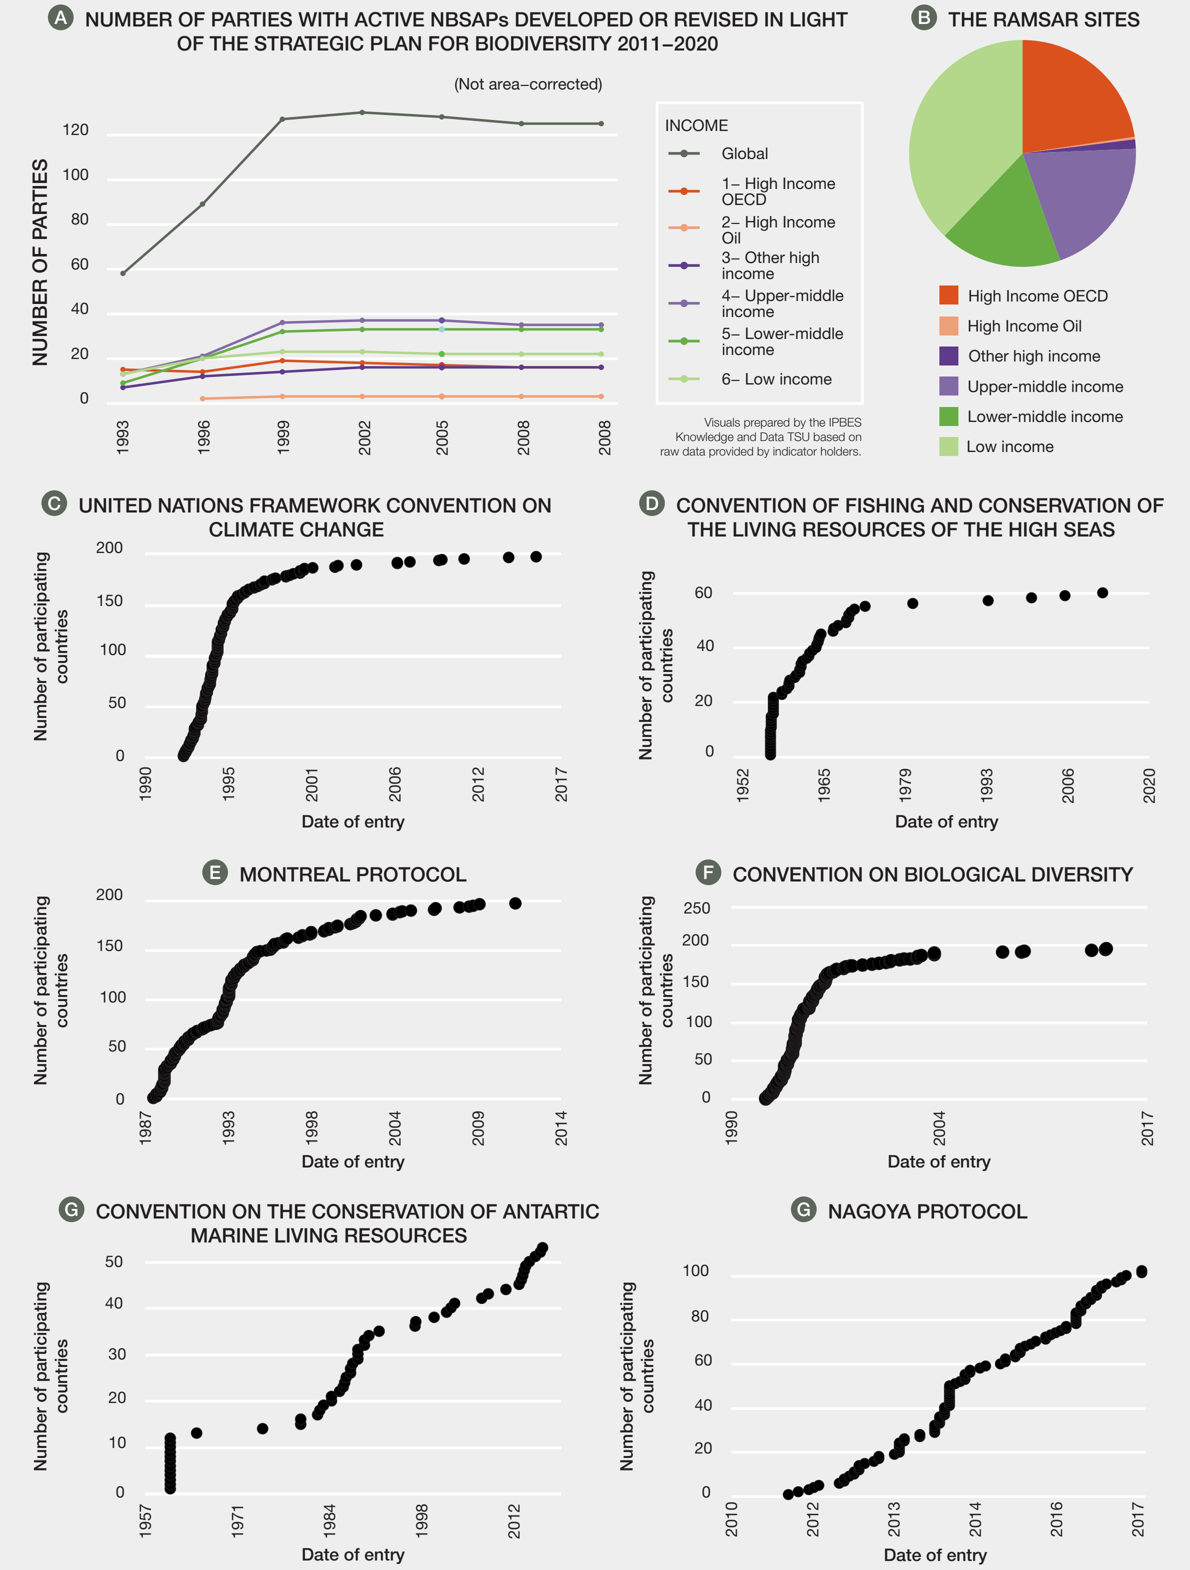

Figure 2 1 11 **Temporal trends in number of parties joining global agreements:**

Average values per country using World Bank income categories for Figures A and B: High Income OECD (a:21, b:) High Income Oil (a:3, b:), Other high income (a:16, b:), Upper-middle income (a:40, b:), Lower-middle income (a:34, b:), Low income (a:27, b:) and Total (a:141, b:). Source: (Australian Government - Department of the Environment and Energy, 2017; CBD, 2018a, 2018b; UN, 1966; UN Secretariat to the Antarctic Treaty, 2018).

Fisheries Management Organizations (RFMOs) were established to manage highly migratory stocks, such as different tuna species. Around this time, global fishing effort shifted to the Southern Hemisphere, as key fish stocks in the Northern Hemisphere stocks were depleted. Latin American countries then began to claim jurisdiction over the 200 miles extending from their coastlines. Expansion of global fishing fleets prompted the establishment of national sovereignty over coastal waters via the United Nations Conference on the Law of the Sea convention (meetings 1958 to 1982). Exclusive economic zones (EEZs) were established, giving jurisdiction over 200 nautical miles from national coasts. This allowed countries to manage fish stocks in their national waters using licensing systems to restrict or more generally manage both national and foreign fishing vessels in those waters.

Other key international agreements within this sector include the UN Convention on Fishing and Conservation of Living Resources of the High Seas, as well as the FAO Code of Conduct for Responsible Fisheries that promotes a 'precautionary approach'. In addition, the Convention on the Conservation of Antarctic Marine Living Resources established an MPA and the closures of bottom-trawling fisheries to protect resources located outside of national jurisdictions (Caddy & Cochrane, 2001; Wilen *et al.*, 2012; Wright *et al.*, 2015).

International cooperation on transboundary environmental degradation (water, air, CO_2) also has been studied (Barrett, 1999, 2001, 2013; Barrett & Stavins, 2003; Wood, 2011). Cooperation can be 'strategic', depending on beliefs about the decisions of others, creating an obvious setting for spillovers from one country's decisions. While getting cooperation can be daunting if goals are insufficient or too ambitious (Barrett *et al.*, 2006; Vale, 2016), participation tipping points can be reached if enough countries join then (Barrett & Dannenberg, 2015; Green, 2015).

Alternatively, agreements among smaller sets of countries with common interest are highlighted. Though not global solutions, they are superior to countries acting alone (Finus *et al.*, 2009; Tavoni, 2013). Multiple such small agreements, each acceptable within like groups, could constitute complementary elements in global political frameworks for environmental governance (Falkner *et al.*, 2010; Hale & Roger, 2014). Technical innovations matter greatly. Barrett *et al.* (2006) shows that technologies with increasing returns can succeed where coordination by countries is possible: if the treaty enters into force only after a specific number of countries has signed on, then no country loses and each country could gain from signing on after that number.

Focusing on biodiversity in particular, CITES is an example of a form of global governance that is evolving in implementation via interaction with its member states, in light of species scarcity. CITES is an agreement between governments to ensure that international trade in specimens of wild animals and plants does not threaten their survival. Its implementation responds to changes in nature to ensure that biodiversity is not compromised. UN member states signed CITES, then established a mechanism to implement the agenda. For example, the government of India signed and ratified in 1976, then established a CITES Management Authority, coordinated by a Director in Wildlife Preservation, alongside authorities including the Wildlife Crime Control Bureau.

Efforts to enforce CITES' provisions have affected how species-based trade and illegal activities are regulated, with provisions to reform national-level environmental legislation in conjunction with the CITES Secretariat (administered by UNEP in Geneva). For instance, India amended its Wild Life (Protection) Act of 1972 to integrate CITES provisions, then took several initiatives to build capacity for implementation, such as establishing a self-sustaining multilateral mechanism (including China, Germany, India, Kenya, South Africa, Thailand, Uganda and United States) for funding a program to Monitor the Illegal Killing of Elephants (MIKE) in Asia. Along these lines, Nigeria put in place guidelines for wood-product vendors to require letters of support and CITES permits. That may indicate a shift to sustainable harvesting, updated per species' threats. Yet impacts remain unclear for these iterations between countries and international instruments.

2.1.11 INDIRECT-TO-DIRECT DRIVERS: ACTIONS THAT DIRECTLY AFFECT NATURE

Given the demands for a good quality of life, and characteristics of society including governance, individuals and societies undertake actions with intentional and unintentional impacts on nature. Each action can be carried out in different ways, with different impacts on nature and on actors. Major trends for actions and impacts are shown in **Figure 2.1.12** for groups of countries with different development levels (https://www.un.org/en/development/desa/policy/wesp/wesp_current/2014wesp_country_classification.pdf), revealing the global trends (see Figure S17). Actions (economic sectors) and their direct consequences on ecosystems are discussed below.

2.1.11.1 Fisheries, Aquaculture and Mariculture

Fisheries, aquaculture and mariculture play an increasing role in food security, livelihoods, and the global economy, yet fish stocks are being depleted. Fish provide ~20% of all animal protein globally (FAO, 2009b), and almost 60 million people were engaged in fisheries and aquaculture in 2012, most in Asia (84%) and Africa (>10%) (FAO, 2014). Value added in fisheries in 2011 was estimated to be over US$24 billion, i.e., 1.26% of the GDP of all the African countries.

Industrial fishing's footprint is 4 times that of agriculture, covering at least 55% of oceans' areas. Data from a new digital platform (Global Fishing Watch, 2018; Kroodsma *et al.*, 2018; McCauley *et al.*, 2016) allows for remote monitoring of vessels in the sea, providing new insights **(Figure 2.1.13)**. They permit monitoring of the 2012–16 activities of more than 70,000 industrial fishing vessels. As much as 85% of the fishing in remote parts of the oceans was by only five countries (China, Spain, Taiwan, Japan and South Korea). Global fishing hot spots include the northeast Atlantic (Europe) and northwest Pacific (China, Japan, and Russia), plus upwellings off South America and West Africa **(Figure 2.1.13)**. Lowest efforts were in the Southern Ocean, the northeast Pacific and the central Atlantic, and in the exclusive economic zones (EEZs) of many island states **(Figure 2.1.13)**.

Smal-scale or non-industrial fisheries (SSF) comprise a large share of global fisheries. SSFs account for over 90% of commercial fishers (over 100 million people), and nearly half (46%) of the global fish catch (Basurto *et al.*, 2017; Béné, 2008; World Bank, 2012). SSF practices entail less bycatch, less destructive gear, and less fuel consumption (Pauly, 2008), more sustainable than industrial fisheries, though with considerable ecological impacts (Alfaro-Shigueto *et al.*, 2010; McClanahan *et al.*, 2009). Yet, SSF statistics are often unreported (FAO, 2016b; Salas *et al.*, 2007). FAO efforts to elevate the profile of SSFs (FAO, 2014) have been improving the reliability and the quality of SSF data (FAO, 2016b).

While three-quarters of major marine fish stocks are fully or over-exploited or depleted —3% underexploited, 20% moderately, 52% fully, 17% overexploited, 7% depleted, 1% recovering from depletion (FAO, 2005, 2016b), efforts are being undertaken to shift trends and increase sustainability. The global fishery community is incrementally adopting sustainable development principles since 1992, including under the umbrella of mainstreaming biodiversity (Friedman *et al.*, 2018). Cross-sectoral cooperation has also been particularly critical to address disagreements, with approaches increasingly including biodiversity considerations. Conservation increasingly adopts more socially inclusive approaches. Efforts on sustainability relate to the Maximum Sustainable Yield (MSY; UN, 2017), which sets harvesting standards. Also, ecologically sound farming systems include aquaculture and integrated farming systems. For instance, in December 2016, 296 fisheries in 35 countries were certified as sustainable by the Marine Stewardship Council Fisheries Standards aiming for healthy ecosystems and long-term sustainability of stocks. Marine spatial planning to reduce conflicts between large- and small-scale fisheries as well as other sectors is increasing in many parts of the world (Douvere & Ehler, 2006). Such planning encompasses ecosystem-based management (FAO, 2003; see McLeod & Leslie, 2009), marine protected areas (FAO, 2011a), and an adaptative management perspective based on participation of the diverse stakeholders (Ehler & Douvere, 2009; Levin *et al.*, 2018).

In contrast, knowledge of inland fisheries is limited, despite societal and ecological significance. Inland fisheries are in lakes, reservoirs, rivers, floodplains, wetlands, lagoons and estuaries. Their economic and food security contributions can be invisible (Lynch *et al.*, 2016, 2017; Youn *et al.*, 2014), with inaccurate or unavailable data (Bartley *et al.*, 2015). Currently, global estimates (FAO, 2016b) suggest a production of about 11.9 million metric tons, over 12% of fisheries production. Over the past decade, the outputs from inland fisheries rose by over 30% despite threats from dam construction, water withdrawals, and pollution. For instance, migratory Caspian sturgeons lost 90% of their habitats (Barannik *et al.*, 2004).

Global fish production is concentrated in a few countries and firms. Overall, Asia accounted for 89% by volume and 79% by economic value in aquaculture (Bostock *et al.*, 2010). Thirteen large corporations from seven countries control a significant fraction (11–16%) of global marine catch (9–13 million tons) and control the largest stocks, with the highest economic values (19–40%), while operating through an extensive global network of subsidiaries (Österblom *et al.*, 2015).

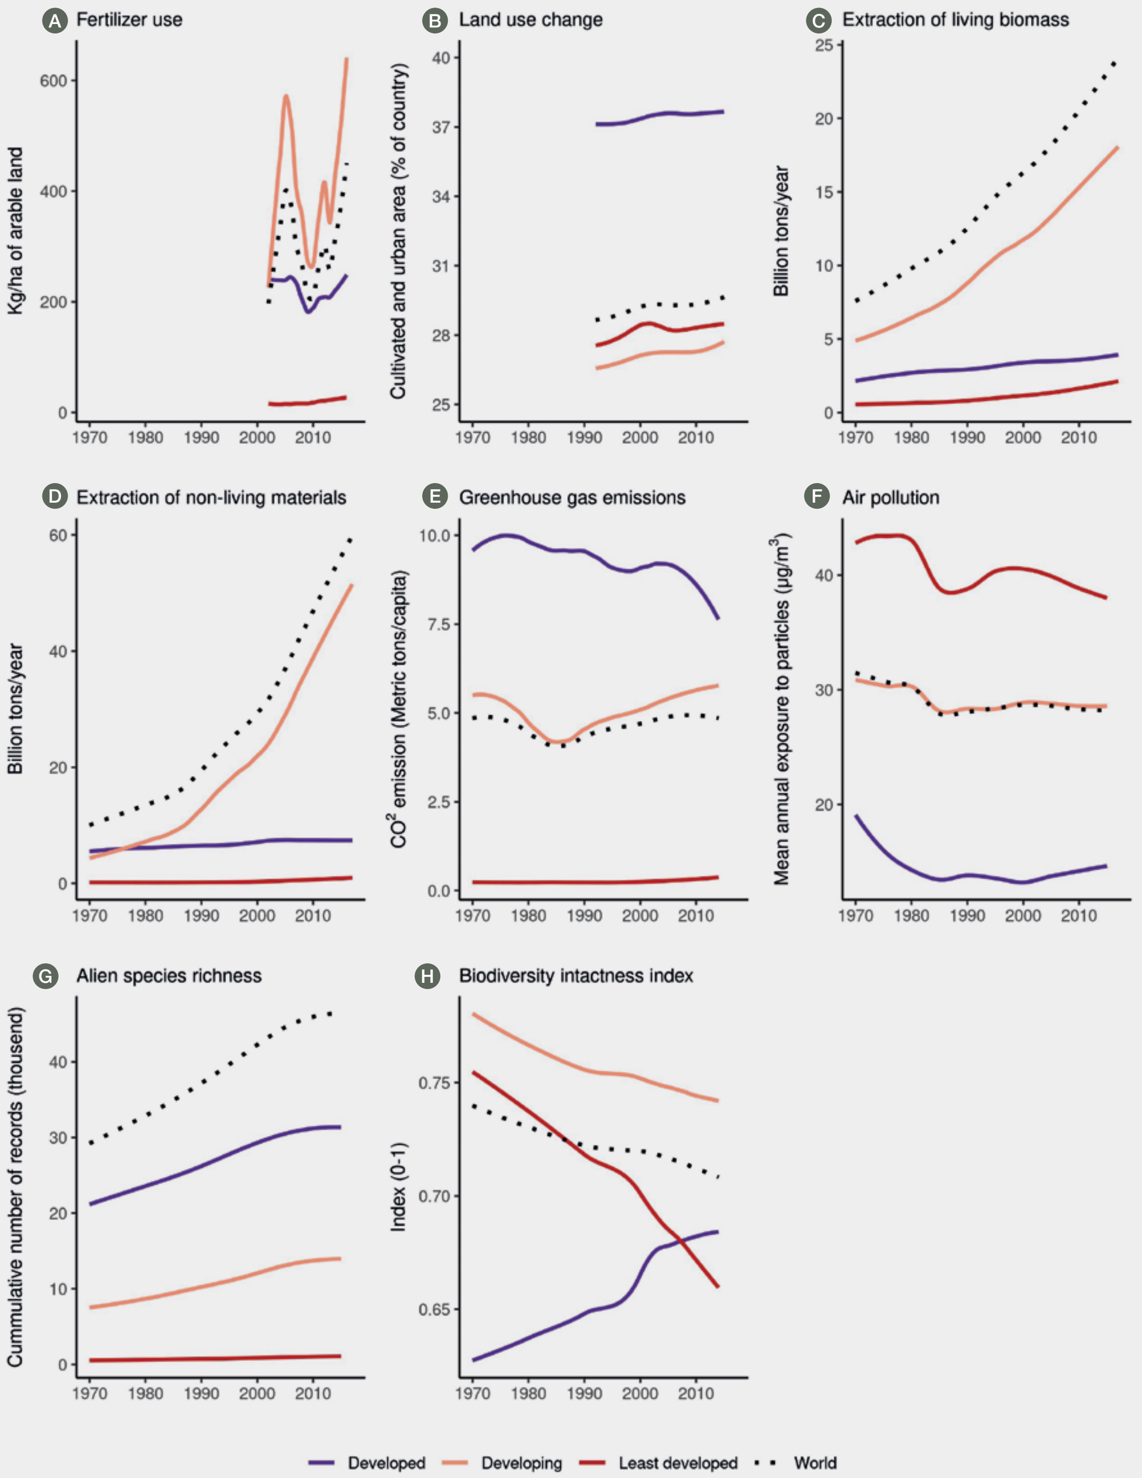

Figure 2 1 12 **Temporal trends for selected indicators of actions and direct drivers.**

Data shown are trends, per country, averaged (A, B, E, F, H) or totaled (C, D, G) by development categories: A **Fertilizer use:** Fertilizer consumption measures the quantity of plant nutrients (kg) used per unit of arable land per year; B **Fraction of cultivated and urban area:** Proportion of total area of country with cultivated and urban land cover, based on ESA CCI Global Land Cover v2.0.7; C **Extraction of living biomass:** Millions of tons per year extracted from agriculture, forestry, fishing, hunting and other types of living biomass; D **Extraction of nonliving materials:** Millions of tons per year extracted of fossil fuels, metal ores, and minerals for construction and industry; E **Per capita greenhouse gases emissions:**

metric tons of CO_2 emitted per year; E **Air Pollution:** mean annual exposure to particles larger than 2.5 micrometer of diameter in micrograms per cubic meter; G **Alien species:** Cumulative number of first records of alien species; H **Biodiversity intactness index:** relative change in abundance of native species as compared to a pristine system. Source: ESA (2017); FAO (2018b); Newbold *et al.* (2016); Ritchie & Roser (2018); Seebens *et al.* (2017); World Bank (2018c); WU (2017).

Colored scale shows the number of messages recorded over the year in a cell. The boundaries, names and designations used do not imply any form of official endorsement or acceptance by the United Nations. Source: (Kroodsma *et al.*, 2018; UN, 2016d).

The contribution of aquaculture to global fish production is increasing, with an average annual expansion rate of 9.5% and 6.2% in 1990–2000 and 2000–2012, respectively (FAO, 2014). Yet its contribution to the total fish production has widely fluctuated, especially after 2000 (OECD, 2016). This expansion has incorporated an increasing list of species with different regional and economic importance values (FAO, 2014). The production of aquafeed has increased four times to 29.2 million tons by 2008 (UN, 2017) and it is contributing to national economies (US$6.4 billion in 2014), particularly within developing countries. Fishmeal and fish oil are produced mainly from harvesting stocks of small, fast reproducing fish (e.g., anchovies, small sardines and menhaden). Aquaculture is also emerging as an ecologically friendly alternative (Cottier-Cook *et al.*, 2016), although its growth is having mixed effects upon coastal and marine ecosystems (Figure S19). For instance, selective fish farming for high-performance breeds affects species diversity (Zhou *et al.*, 2010). Aquaculture also contributes to coastal habitat destruction via both wastes (nutrients, feces, antibiotics) disposal and introduction of invasive alien species and pathogens. Aquaculture also contributes to further depleting fish stocks, due to the large fish meal and fish oil requirements (Naylor *et al.*, 1998, 2000). These effects are species dependent. For instance, shrimp and salmon farming have net negative effects, while carp and mollusk farming have net positive effects on global fish supply and food security (Naylor *et al.*, 2000)**.**

2.1.11.2 Agriculture and grazing (crops, livestock, agroforestry)

The wide range of agricultural systems includes plant and animal-based systems, mixed farming, and newly emerging organic, precision, and peri-urban agricultural systems. Agroecosystems cover close to 40% of lands and continue to expand as there is a need to provide food, fuel and fiber for the 9–12 billion people expected by 2050 (Nyaga *et al.*, 2015). More than 175 species constitute the most frequently and extensively cultivated species, globally, with large variations in agricultural yield (Monfreda *et al.*, 2008). While agriculture's inputs and its outputs constitute the bulk of world trade, most food produced today is consumed domestically.

In 2000 there were 15.0 million km^2 of cropland (12% of the Earth's ice-free land surface) and 28.0 million km^2 of pasture (22%) (Ramankutty *et al.*, 2008). Impacts from agriculture are huge (HLPE, 2013; Pretty *et al.*, 2006; SDSN, 2013), e.g., 70–90% of withdrawals from rivers, lakes, and aquifers (Foley *et al.*, 2005) and 25% of global greenhouse gas (GHG) emissions from land clearing, crop production, and fertilization (Burney *et al.*, 2010). During 1980–2000, most new agricultural lands in the tropics came at the expense of intact or disturbed forests (Gibbs *et al.*, 2010). In Africa, agricultural expansion is farming for subsistence (small plots for sorghum, maize, millet) but sugarcane and soybeans are responsible for most agricultural expansion in South America. Rice, wheat, millet, and sorghum dominate South Asia, consistently over time, though tree plantations increased from ~11 to ~17 million hectares between 1980 and 2000, with oil palm plantations responsible for over 80% of this expansion, particularly since the 1990s (Gibbs *et al.*, 2010; Ramankutty *et al.*, 2008).

Agricultural intensification has also increased, with mixed social and ecological outcomes. For instance, water withdrawals and pesticide use have doubled, fertilizer use has tripled, chicken density has increased 10-fold, and cattle density has risen by 20% (Figure S20). Between 1985 and 2005 crop production rose 47% as yields rose 28%, while global crop and pasture lands rose 3%, largely in the tropics (Foley *et al.*, 2011; Poore & Nemecek, 2018). Extensive grazing occurs in 91% of lands, with intensive rising to 9%, largely for livestock production (IPBES, 2018a). An analysis of 60 cases found that agricultural intensification rarely leads to win–win social-ecological outcomes, often increasing food or provisioning services with mixed outcomes for regulating services, that support long-term productivity, and overall well-being (Rasmussen *et al.*, 2018).

Livestock production uses a third of crop production for feed and three quarters of land in total, with consequences for nature as animal-based foods, and especially beef, require more water and energy than plant-based foods (Ranganathan *et al.*, 2016). This all translates into greenhouse gas emissions as well (FAO, 2008). Substantial variation exists in conversion efficiency (i.e., animal products divided by feed to produce them), from 8–10% in Europe to only 1–2% in sub-Saharan Africa, Latin America and South Asia (Krausmann *et al.*, 2008).

Diverse agricultural systems exist, though, with combinations of short-lived and perennial crops together with timber and non-timber products developed over centuries in rural areas, including by IPLCs. Varied agro-silvo-pastoral systems allow maintenance of biodiversity, lower nature's degradation and provide a wide range of material, regulating and non-material contributions (Altieri *et al.*, 2012; Balvanera *et al.*, 2014; González-Esquivel *et al.*, 2015; Kanter *et al.*, 2018; Moreno-Calles *et al.*, 2015). Yet, the associated local and indigenous ethnoecological knowledge is being eroded by migration, urbanization, affected by extension programs, and by agricultural policies oriented to expand the areas under intensive pesticide-based monocultures in support of the international trade of agricultural commodities. For instance, a 70% decline in the cultivation of native plant varieties was observed in the Asia and the Pacific region, with reductions in genetic resources (IPBES, 2018b).

Still, small landholders play crucial roles. It is estimated that small-scale (< 2ha) farms generate ~30% of crops and food supply, using 24% of land, and with high agrobiodiversity (Ricciardi *et al.*, 2018). They also play a key role in maintaining the genetic diversity of managed species (IPBES, 2018b). In Mexico, for example, small-holders cultivating rainfed maize reach yields equal to 3 t/ha, and can feed more than half of the country's population while having a large genetic diversity (Bellon *et al.*, 2018).

As pristine areas fall, the design and management of sustainable agroecosystems (Altieri, 1995) has been applied in agroforestry, sustainable intense agriculture, and integrated pest management (Barrios *et al.*, 2018) with gains for biodiversity and ecosystem services (Bawa, 2004; Du Toit *et al.*, 2004; IAASTD, 2009; Nyaga *et al.*, 2015; Pimentel *et al.*, 1992; Schroth *et al.*, 2004; Tscharntke *et al.*, 2005; Vandermeer & Perfecto, 1995). Zomer *et al.* (2016) find for 2010 that over 43% of agricultural lands had at least 10% tree cover (FAO forest definition). This can connect forests, as is the case within the Mesoamerican Biological Corridor (MBC) launched in 1990 to link forests in northern Colombia with those of southern Mexico.

Organic agriculture has also developed rapidly in more recent decades, including in larger-scale systems, with a focus on utilizing lower off-farm inputs and, where possible, cultural, biological and mechanical pest management. By 2006, such practices covered over 31 million ha in 120 countries (Alexandros *et al.*, 2012). With variable outcomes, they may improve biodiversity, soil and water quality and nutritional value, although not always providing higher yields and lower consumer prices when compared to large-scale monocropping (Seufert & Ramankutty, 2017).

2.1.11.3 Forestry (logging for wood & biofuels)

Between 1990 and 2015, global forest area fell from 4.28 billion to 3.99 billion ha, while the area of planted forests rose from 167.5 to 277.9 million ha (Payn *et al.*, 2015). Forests currently cover one-third of terrestrial area (FAO, 2012a), and a large fraction of people depend at least in part on forests (FAO, 2012a). A challenge has been to manage forests to sustain livelihoods and yet maintain regenerative capacity to ensure long-run survival of forests (MacDicken *et al.*, 2015).

Global harvests of roundwood in 2017 were estimated to be 3.9 billion m^3 of which 1.9 billion were industrial and 1.9 billion were fuelwood (~50% respectively) (FAO, 2018c). Harvests of industrial roundwood are falling in high income OECD countries but increasing in lower-middle and upper-middle income countries (Figure S22). Asia has the highest proportion of agricultural land (52%) and the lowest of forest (19%). Temperate areas within East Asia, Europe, North America, and Southern and Southeast Asia show the largest increases in planted forests. Native species are found within 80% of the planted forests, while introduced species dominate in South America, Oceania and Eastern and Southern Africa as a result of industrial forestry there.

Much forest biomass generates energy, as solid, liquid and gaseous fuels, accounting for 14% of the global energy mix in 2014 (IEA, 2017), while generating greenhouse gas emissions. Between 1960 and 2014, bioenergy use rose 2.7-fold, most in Africa (4.1-fold), yet the share of bioenergy in energy supply declined (15% to 10%) over the same period (De Stercke, 2014). Global use of fuelwood peaked in the mid-1970s and has been falling since the 1980s. Over a quarter of global fuelwood harvested in 2009 was deemed unsustainable, with geographical variations. Over 250 million rural people live in fuelwood-scarcity "hotspots", mostly in South Asia and East Africa (Masera *et al.*, 2015). Of all wood in fuel, about 17% is converted to charcoal, of which production rose over 3-fold during 1961–2015 (FAO, 2016a) given the population growth, poverty, urbanization and prices of alternatives (FAO, 2017a).

Over decades, and centuries, the maintenance of forest cover and biodiversity has been possible, in cases at least, alongside the harvesting of timber and non-timber forest products. Experiences from implementing sustainable forestry in past decades shows that it can achieve higher levels of success where attention is given to planning, establishing permits, and legal rights (MacDicken *et al.*, 2015). As discussed above, forest certification standards for sustainable harvest have been developed by several organizations, including the Forest Stewardship Council (FSC, 2018) and the Programme for the Endorsement of Forest Certification (PEFC, 2018). For tropical forests, such certifications have, in cases, provided varied environmental and social benefits for local communities, with lower short-term profits (Burivalova *et al.*, 2017).

Sustainable community forestry is found in Latin America (Mexico, Central America, Colombia and Peru), Canada and the US (Gilmour, 2016; Merino & Cendejas, 2017; Nagendra, 2007), while sustainable family forestry occurs in Northern and Central Europe (Finland and Austria). Often, community forest is managed within agroforestry systems such as for shade coffee and cacao. For instance, within the lands of IPLCs in Mexico and Central America, there is evidence that community forestry is as efficient as protected areas in preserving forests and conserving biodiversity (including both bird and mammal species) and reducing rates of greenhouse gas emissions (Bray & Merino-Pérez, 2004; Duran-Medina *et al.*, 2005; Merino & Cendejas, 2017; Merino-Pérez, 2004). However, economic and environmental benefits of community management are still understudied and, in the case of tropical forests, its social impacts could be either positive or negative (Burivalova *et al.*, 2017).

2.1.11.4 Harvesting (wild plants and animals from seascapes and landscapes)

Harvesting and use of non-timber forest products (NTFPs) is a core component of livelihoods for forest-dependent communities around the world. About 350 million people in or adjacent to forests depend on NTFPs for subsistence and income (World Bank, 2004). NTFPs include any biological resources found in forests other than timber (e.g., seeds, oils, foliage, game animals, medicinal plants, spices, bark, mushrooms, fuelwood). Poor rural populations heavily depend on medicinal plants when healthcare is limited, with Africa being most dependent (IPBES, 2018b).

Data are patchy, as consumption is often local, outside markets, and not within national statistics. A meta-analysis of 51 studies in 17 countries found that NTFPs represented, on average, 22% of total income for sampled populations. They also play key roles as equalizers of local income distributions (Vedeld *et al.*, 2007) because the poor rely more on them. A study (Belcher *et al.*, 2005), of close to 100 cases across Africa, Asia and Latin America supports that the households with lower incomes relied more on NTFPs for their livelihoods – such that degradation and overexploitation impact the rural poor more (Belcher *et al.*, 2007; Shackleton & Shackleton, 2004), especially the old and the young.

Some NTFPs have large markets. For instance, maple syrup earned ~US$350 million in 2015, up 18% from 2011. Canada produced 82% of it, followed by the US (7.6%) and Germany (2.3%) (Barlow *et al.*, 2015). Rattan from humid and sub-humid forests in Indonesia (80%) earned over US$70m (62,000 tons) in 2008, down 70% from 2000 (Hirschberger, 2011). Empirical evidence is biased towards such traded NTFPs, which are a small fraction (Belcher *et al.*, 2005). While commercialization may maintain and even improve livelihoods, market chains with many intermediaries can lower local economic returns and increase overexploitation of the products (Buda Arango *et al.*, 2014; Marshall *et al.*, 2006).

Bushmeat is an important source of protein and provides food security and livelihoods for many forest-dependent rural and urban populations in low- and lower-middle income countries. In the tropics, at least 6 million tons of large to medium size mammals, birds and reptiles are harvested every year (Nasi *et al.*, 2011), with 1 to 5 million tons within the Congo Basin alone (Fa *et al.*, 2003; Wilkie & Carpenter, 1999). About a third is commercialized and reported in national statistics (Karp *et al.*, 2015; Nasi *et al.*, 2011). Many species can survive high offtake but for slow-breeding species even low offtake can be devastating (Van Vliet *et al.*, 2010, 2007). Some literature suggests that the rare species are seldom targeted and are a small share of offtake (Abernethy & Ndong Obiang, 2010; Nasi *et al.*, 2011; Van Vliet *et al.*, 2010), yet a large number of primate species are threatened.

In high and middle income countries, hunting, and trophy hunting in particular, now are mostly recreational, aimed at large game species (bears, wolves, lynx, red deer, wild boar) and at birds (ducks, geese, waders, doves, passerines). Around 6 million wild ungulates are harvested every year, with a mixed set of motivations (Bauer & Giles, 2002). Yet hunters have declined in many parts of Europe and the US. Game fishing targets larger members of many species, which tend to be the most fecund, yielding disproportionate impacts on biodiversity. A large number of species (85) targeted by the International Game Fish association are considered 'threatened' by IUCN. In contrast, most Arctic hunting and fishing is for local consumption – often regulated separately (CAFF, 2013) – with nutritional and cultural significance, especially for Indigenous Peoples.

2.1.11.5 Mining (minerals, metals, oils, fossil fuels)

Mining activities directly and indirectly affect the livelihoods of most people around the world, via contributions to the production and use of minerals, metals, oils and fossil fuels. Hundreds of mineral commodities have uses in energy, construction, manufacture, and industrial processes. Mining contributes a large fraction of the world's GDP, particularly among emerging economies, with over 60% of GDP for 81 countries in 2014, and more than 17,000 large-scale sites in 171 countries (Matos *et al.*, 2015). Oil, gas, coal and minerals (e.g., bauxite, copper, gold, iron ore, lead, nickel, phosphate rock, silver, tin and zinc) are close to a quarter of natural capital globally, and close to 7% of total wealth (World Bank, 2006). Thus, this is an extremely important economic sector.

Yet, it features imperfections in rights, markets and legal structures. Valuable resources have had destructive consequences as well, such as in Africa's 'diamond wars' (Gylfason, 2009), although systematic quantitative global data on these issues largely are missing. As global gold demand increased after the international financial crisis, within the South American moist forest ecoregions more than 90% of the deforestation linked with gold mining occurred within four major hotspots: Guianan (41%), Southwest Amazon (28%); Tapajós–Xingú watersheds (11%); and Magdalena–Urabá along with Magdalena valley montane forest (9%) (Alvarez-Berríos & Aide, 2015). Some of the more active zones for all this deforestation associated with gold mining deforestation occurred in or within 10 kilometers of protected areas (Alvarez-Berríos & Aide, 2015).

Mineral deposits of *Al, Fe, Cu, Au*, and *Ag* are concentrated in the Andes, Rocky Mountains, North-East America, Australia, South-eastern and Western Africa, Northern and Eastern Europe, and in Eastern and South-Pacific Asia. Globally, bauxite and silver mines are within zones with intermediate to high biodiversity (Murguía *et al.*, 2016). Further, as the ice melts with climate change, new areas are opening up to mining within the Arctic and the Antarctic regions, including with important petroleum reserves in the Arctic (AMAP, 2018).

Surface mining is a driver of land-cover change, pollution of surface and ground water, and air quality degradation, constituting a health hazard in many regions. Although it occupies under 1% of land area, it has negative effects upon vast areas (Schueler *et al.*, 2011; Sonter *et al.*, 2014), locally for biodiversity perhaps more than agricultural expansion (Deikumah *et al.*, 2014). Severe landscape transformations include not only deforestation but also the opening of pits, vast amounts of waste, large quantities used of freshwater, and chemical and physical pollutants released into air, land and water (Palmer *et al.*, 2010). Coal and gold mining (Epstein *et al.*, 2011; Palmer *et al.*, 2010) can severely modify a landscape, including via extensive destruction of forest and the corresponding loss of habitats (Asner *et al.*, 2013; Swenson *et al.*, 2011; Wickham *et al.*, 2007).

Subsequent processing also released carbon dioxide, sulfur dioxide, methane, particulate matter, mercury and other heavy metals, generating acid rain and raising the bioavailability of mercury and other heavy metals (Epstein *et al.*, 2011; Palmer *et al.*, 2010). In the main gold production region of Colombia, gold mining is responsible for the highest reported concentration of mercury in the air (a thousand times above the WHO's allowable level) (Cordy *et al.*, 2011), putting ~150,000 people at high risk of mercury poisoning (Spiegel, 2012). Artisanal and small-scale gold mining is the leading source of anthropogenic mercury emissions globally (UNEP, 2013). Mining also occurs in oceans, in over 50 countries. While seabed mining is a currently relatively small, the growing demand for minerals has led to 18 contracts granted in the last 4 years by the International Seabed Authority (ISA), for ~1 million km^2 in the Pacific, Atlantic, and Indian Oceans beyond any national jurisdiction (Wedding *et al.*, 2015).

While large companies produce most of the minerals traded internationally, small-scale mining is an important economic activity, particularly in the developing world. Many poor rural people see it as a best livelihood option (Spiegel, 2012), yet they may not capture much economic surplus in the value chain (Hilson, 2003; Hinton, 2005). Whole countries rich in minerals have had limited long-term impacts on their economies from mining. Latin America has large deposits of copper, iron, gold and silver. Chile, Bolivia and Peru are the major mining countries of South America. Africa is estimated to have 40% of the world's gold, 60% of cobalt, and 90% of platinum. Yet, booming mining sectors in mineral-rich countries may not have large gains in local communities, especially when also taking into account environment and health impacts (Gordon & Webber, 2008). Many countries have been unable to use mining wealth to greatly boost their economies (Auty, 2006; Sachs & Warner, 1995). Furthering the potential for local net costs, the sector also has been linked to social and environmental conflicts, and illegal activities, with a few large multinational companies controlling large networks of exploration sites with the largest human rights violations (Inter-American Court of Human Rights and Bebbington & Bury, 2013; see sections 2.1.6.3.2 and 2.1.9.1).

2.1.11.6 Infrastructure (dams, cities, roads)

While the development of infrastructure has negative direct consequences on the environment, it has both negative and positive indirect effects (see also sections 2.1.5.3, 2.1.6.2, 2.1.9.1.2, 2.1.11.1). Rivers have been modified for thousands of years to regulate floods and to ensure water supply for irrigation, industries and settlements, recreation, navigation and hydropower generation. Over past decades, the numbers of dams and reservoirs, and their overall storing capacities, have greatly increased. Currently, about 50,000 large dams (higher than 15 m), and an estimated 16.7 million reservoirs (larger than 0.01 ha) hold approximately 8,070 km^3 of water (Lehner *et al.*, 2011). Close to 8% of the world's rivers are affected by cumulative upstream reservoir capacities exceeding 2% of the annual flow. Smaller reservoirs (> 0.5 km^3) account for a small fraction of the water stored, yet substantially affect rivers, increasing their spatial extent (Lehner *et al.*, 2011). These changes have decreased the global annual sediment flux to the coastal zones by 3.7 billion tons, leading to river sediment starvation and thus coastal erosion in delta regions and estuaries with negative consequences upon habitats, while increasing coastal and estuarine turbidity, negatively affecting biological systems. These estuaries and deltas are estimated to concentrate some of the largest population density in the world, including a large share of coastal mega-cities (UN, 2017).

Urbanization has multiple and complex linkages to the environment (Bai *et al.*, 2017; Grimm *et al.*, 2008). Currently, urban areas account less than 3% of the total land area (Grimm *et al.*, 2008; McGranahan *et al.*, 2005), although urban expansion is faster than urban population growth (UN, 2014), often driven by positive feedbacks between urbanization and economic growth (Bai *et al.*, 2012). From 1970 to 2000, urban land use expanded by 58,000 km^2 (Bai *et al.*, 2012; Seto *et al.*, 2011). The expansion of cities is linked to infrastructure to supply demands of urban living (e.g., transportation of people, goods, energy, water), with effects in and beyond the boundaries of urban areas. Growing urban populations create more impervious surfaces, which reduce water infiltration, affecting regional climates and hydrology (Chen *et al.*, 2010a; Tayanc & Toros, 1997; Žganec, 2012). Infrastructure development projects designed to address the supply of natural resources may also displace people, take agricultural land out of production, and alter ecosystems (Liu *et al.*, 2016c; Vitousek *et al.*, 1997b; Zhang, 2009). Yet, urban infrastructure attracts people from rural areas, potentially lessening the land uses in fragile and/or low productivity ecosystems, stimulating ecosystem recovery and improving biodiversity conservation (Aide & Grau, 2004; Grau & Aide, 2007; Grau *et al.*, 2003).

Urbanization is also a major cause of losses of lakes and wetlands in multiple countries (Davis & Froend, 1999; Prasad *et al.*, 2002; Wang *et al.*, 2008). Production and consumption in cities can exacerbate air and water pollution – with negative health consequences (Guo *et al.*, 2013; Liu *et al.*, 2016b; McMichael, 2000; Zhu *et al.*, 2012). Urban land expansion also reduces habitats, particularly in biodiversity hotspots (Elmqvist *et al.*, 2013; Seto *et al.*, 2012). Urbanization and urban activities shift spatial and temporal patterns of rainfall (Shi *et al.*, 2017), while physical structures influence regional temperatures through heat islands (Giridharan *et al.*, 2004; Sobstyl *et al.*, 2018). On the other hand, cities can also be champions of environmental stewardship, for instance by building flood-resilient cities and reducing varied emissions of greenhouse gases (Bai *et al.*, 2018; Solecki *et al.*, 2018). Biodiversity friendly cities are also now found (Botzat *et al.*, 2016).

Roads and transportation infrastructure have been associated with both increased pressures upon forests and habitats or, in contexts, relocation of pressures away from nature (Benítez-López *et al.*, 2010). New roads certainly have led to losses of forest (Boakes *et al.*, 2010; Laurance *et al.*, 2015) but with highly varied impacts depending on their contexts – from large losses to no net effects, across tropical forests in Latin America, to even some positive effects in more highly populated and developed areas, such as within India. The indirect effects of transportation investments through transport costs, and related responses, can be much bigger than the direct effects of projects (Edwards *et al.*, 2014; Weng *et al.*, 2013).

Increasing human encroachment, land reclamation, and coastal development have big impacts on coastal environments (UN, 2017) including on nature, e.g., mangroves that help with resilience. To meet growing land demand for housing and recreation, industry, commerce, and agriculture, large-scale land reclamation projects are increasing along coasts, although coastal protection is also increasing. Large-scale dredging has occurred in several countries in Asia and the Middle East, beyond the near-shore environments, for creation of airports, tourism facilities and islands. Land reclamation is linked to the degradation of wetlands, seagrass beds and decreased coastal water quality, with negative impacts on regional groundwater regimes discharges to the coasts.

Challenges posed by the growth of infrastructure vary by country (Bai *et al.*, 2017; McGranahan *et al.*, 2005), typically with more and better infrastructure as income rises (World Bank, 1994). High income countries have built more energy and telecommunications connections, as well as more extensive transport networks in locations with a higher density of population and industry. In contrast, while infrastructure has expanded tremendously in many rapidly growing cities and peri-urban settlement in Africa and South and East Asia, it still lags the growth of population and service demands – leading to local environmental degradation – while the inadequate design and maintenance of that new infrastructure lead to its severe deterioration and significantly reduced lifespans. Urban growth within the less-developed countries also brings complex challenges, as for increasing the provision of basic services, such as clean water and sanitation (Cohen, 2004, 2006; Elmqvist *et al.*, 2004; Hardoy *et al.*, 2013; Seto *et al.*, 2013; UN, 2014; World Bank, 2015b; Young *et al.*, 2009), although such challenges have also offered opportunities for locally developed solutions (Nagendra *et al.*, 2018).

2.1.11.7 Tourism (intensive and nature-based)

Tourism has dramatically grown in the last 20 years. Total international departures and arrivals tripled globally, with greater increases from high income and upper-middle income countries (Figure S23). Much is domestic, e.g.: 3,260 million versus 29 million international for China; and 1,600 million domestic tourism trips versus 70 million international for the US (UN, 2017).

Between 2009 and 2013, tourism's global carbon footprint rose from by 40%, from 3.9 to 4.5 $GtCO_2$-eq, accounting for ~8% of global greenhouse gas emissions (Lenzen *et al.*, 2018), with transport a big contributor. In 2010, tourism required 16,700 PJ of energy, 138 km^3 of fresh water, 62,000 km^2 of land, and 39.4 Mt of food (Gössling & Peeters, 2015). Yet impacts vary considerably: one-night accommodations require 3.7 - 3,700 MJ of energy depending on the luxury conditions of accommodations and transport. Largest increases have been observed for the most resource-demanding options for the growing global class of wealthy travelers (UN, 2017). Most of the footprint of tourism is exerted by high income countries. These rapid increases in demand are effectively outstripping decarbonizations of tourism-related technology (Lenzen *et al.*, 2018).

Demands for nature-based and eco-tourism also have risen. While the latter aims for consistency with conservation by operating at small spatial scales to minimize ecological and social impacts, the former often operates at larger spatial scales and promotes national development objectives (Brandon, 1996). Their effects are, thus, quite different. The number of visitors to 280 protected areas within 20 countries has been increasing over time in all countries, particularly in those with lower income levels – with the exception of the United States and Japan (Balmford *et al.*, 2009).

2.1.11.8 Relocations (of goods and people)

Transportation of goods and people has risen drastically in recent decades (see also 2.1.11.6). The number of air flights has doubled, globally, and tripled for high income OECD countries (Figure S23), while seaborne carriage of oil has doubled, general cargo has quadrupled, and the carriage of grain and minerals has nearly quintupled. Voyage lengths also have increased (UN, 2017).

Relocation of goods and people has direct, indirect and cumulative impacts on nature (Rodrigue *et al.*, 2016). Noise and toxic emissions – e.g., carbon monoxide – directly cause harm. Catastrophic events involving ships (such as collisions, fires, foundering, wrecks) produce serious direct impact on marine ecosystems (UN, 2017). Indirect effects include chronic impact along frequent trade routes **(Figure 2.1.13)**. Cumulative impacts include those upon the global climate, with 15% of the global CO_2 emissions associated with the transportation sector (Rodrigue *et al.*, 2016), and more than 3.5% of climate forcing attributed to air transportation (Lee *et al.*, 2010).

Introduction of invasive alien species is linked to transportation of goods and people. In both the 20th and 21st centuries, trade was one of the most important factors in the widespread distribution of invasive alien species in both aquatic and terrestrial ecosystems (Hulme, 2009; Seebens *et al.*, 2016) (Early 2006). Accidental introductions of invertebrates and algae had steep increases recently, as those species are difficult to regulate and are closely associated with increasing human activity such as trade, migration, and tourism (Hulme, 2009; Kowarik, 2011).

2.1.11.9 Restoration

With degradation currently impacting the well-being of at least 3.2 billion people, with losses of more than 10% of the annual global gross product (IPBES, 2018a), there is an urgent need for restoration to avoid biodiversity loss, mitigate climate change, and ensure continued global 'life support' (Aronson & Alexander, 2013; Navarro *et al.*, 2017). Sustainable land management practices, with restoration actions to avoid, reduce and reverse land degradation, have been shown to provide benefits that exceed their costs in many places, though their overall effectiveness is context-dependent (IPBES, 2018a). While financial costs are easy to quantify and can seem high, assessing restoration's short-, medium-, and long-term effects on nature's contributions is challenging. They are not all perceived and valued (IPBES, 2018a).

While recoveries due to restoration of ecosystems and landscape may not be complete (Benayas & Bullock, 2012; Jones *et al.*, 2018), they yield multiple direct and indirect benefits for nature and people: increased material benefits from nature; climate regulation; and also spiritual gains (Benayas & Bullock, 2012; Brancalion *et al.*, 2014; IPBES, 2018a). Restoring the structure and function of degraded ecosystems contributes to longer-term ecosystem resilience (Kaiser-Bunbury *et al.*, 2017; Suding, 2011) as well as to short-term mitigation and adaptations to climate change (Locatelli *et al.*, 2015). Restoration is an obvious complement to conservation for biodiversity (Possingham *et al.*, 2015) and ecosystem services. Ultimately, its goals depend on the extent and nature of degradation and local needs and decision processes. Recovery of the prior "intact" ecosystem may not be possible, or desirable, in some contexts (Hobbs *et al.*, 2014).

International conventions recognize the importance of restoration at national and global scales. Restoration is a key piece of Aichi Biodiversity Targets 14 and 15 established by the Convention on Biological Diversity (CBD). Ecosystem- and landscape-scale restorations are also approaches of the UN Convention to Combat Desertification, UN Convention on Climate Change, Ramsar Convention on wetlands, Convention on Migratory Species, and Sustainable Development Goals. The Bonn Challenge to restore 150 million hectares of forest 2020 was expanded by a United Nations' New York Declaration on Forests to restore 350 million ha by 2030 (IUCN, 2015). This is not just to plant trees but also to use regenerated forest sustainably, manage tree plantations, agroforestry and agricultural systems, and protect wildlife reserves with ecological corridors or river or lakeside planting to protect water (IPBES, 2018a). No similar global-scale challenge has yet been proposed for restoration of non-forest ecosystems.

Restoration is implemented by state agencies, local communities, non-government organizations, and the private sector. Approaches range from passive to active interventions, with distinct costs, limitations, and outcomes. Passive approaches that rely on natural recovery mechanisms have the highest rates and extent of recovery overall (Jones *et al.*, 2018), particularly for tropical forests (Crouzeilles *et al.*, 2017). Interventions can focus on specific habitats and ecosystems or at the scale of landscapes, encompassing mosaics of different land uses, ecosystems and land covers.

Yet large gaps remain between restoration targets and achievements, reflecting gaps in capacity, finance, policy, and enforcement (Stevens & Dixon, 2017). Restoration is legally mandated in some countries (e.g., Brazil, China), particularly after certain activities (e.g., mining or wetland drainage or as related to required protections for rivers and streams). Compensatory restoration, required in some countries, requires the party responsible for ecological damage to compensate the public for ecosystem services loss (Rohr *et al.*, 2018). In other cases, biodiversity offsets create a mechanism for off-site restoration to compensate for the biodiversity losses caused by development projects. For example, to offset vegetation losses due to industrial development of oil palm during 1973–2013, the industry would need to restore natural vegetation across 8.7% of Kalimantan (Budiharta *et al.*, 2018) in order to get to no net loss (rather than, e.g., any net gain).

Achieving restoration targets in international treaties and conventions will require avoiding more degradation and conversion of ecosystems, plus effective and long-lasting restoration practices at national scales (Chazdon *et al.*, 2017). With climate and biodiversity policies, this is a basis for progress on sustainable futures (Aronson & Alexander, 2013; Benayas & Bullock, 2012; Brancalion *et al.*, 2014; Budiharta *et al.*, 2018; Chazdon *et al.*, 2017; Crouzeilles *et al.*, 2017; De Groot *et al.*, 2013; Egoh *et al.*, 2014; Hobbs *et al.*, 2014; IUCN, 2015; Jones *et al.*, 2018; Kaiser-Bunbury *et al.*, 2017; Locatelli *et al.*, 2015; Navarro *et al.*, 2017; Possingham *et al.*, 2015; Rohr *et al.*, 2018; Stevens & Dixon, 2017; Suding, 2011; Suding *et al.*, 2015; Verdone & Seidl, 2017).

2.1.11.10 Illegal activities with direct impacts on nature

Illegal activities constitute major threats to nature and livelihoods. In maritime regions, they add to depletion of fish stocks. Coastal zones of developing countries are particularly susceptible to illegal, unreported or unregulated (IUU) fishing that peaked during the mid-1990s. In 2011, IUU fishing was estimated at 26m or 33% of global catch including fish and other marine fauna (UN, 2017) and 20–32% by weight of wild-caught seafood imported to the US (Pramod *et al.*, 2014). Locally, IUU fishing is highest off West Africa, estimated at ~40% of total catch, with 32% in the Southwest Atlantic and as much as 1.5 million tons/year in Indonesia (**Figure 2.1.14**; Agnew *et al.*, 2009). Note that 70% of vessels known to be linked to IUU fishing are flagged under tax-haven jurisdictions (Galaz *et al.*, 2018).

IUU fishing is lucrative, due to high-value species plus no taxes – as is permitted by weak governance (Fisheries and Oceans Canada, 2009). While efforts have improved oceans governance over the last decade, not all regions are overseen by regional fishery management organizations (RFMO) while not all RFMOs are effective in monitoring and controlling IUU fishing. The Agreement on Port State Measures to Prevent, Deter and Eliminate Illegal, Unreported and Unregulated Fishing (PSMA), which came into force in June 2016, has grown to 54 parties (with all 28 EU members counting as just one). Endorsement by 170 states of the FAO Code of Conduct for Responsible Fisheries (CCRF) in 1995 has contributed to lowering IUU fishing. While this is voluntary, Australia, Malaysia, Namibia, Norway and South Africa, have incorporated provisions into national law. Recent improvements in vessel monitoring systems are available, for both larger- and small-scale fishing vessels, providing geo-referenced descriptions of fishing areas and at scales useful for policy (Global Fishing Watch, 2018; Kroodsma *et al.*, 2018; McCauley *et al.*, 2016).

Illegal forestry has important negative consequences on forests, aggregate economic wellbeing, and livelihoods of forest communities (Smith, 2004). Hoare (2015) has estimated that 80 million m^3 of timber was illegally produced in 2013 by the nine main producers in tropical countries. Overall illegal logging is estimated to be 10–15% of global timber production (Brack & Hayman, 2001; RIIA, 2017; SCA & WRI, 2004) though rates of up to 50% are reported for several countries (Guertin, 2003; Tacconi *et al.*, 2003). In 2013, Indonesia (50%), Brazil (25%) and Malaysia (10%) accounted for most of the illegal timber harvests worldwide, with large timber sectors (Hoare, 2015), while Ghana, Cameroon, DRC, Laos, Papua New Guinea and Republic of Congo are also large contributors, with much higher proportions of production being illegal (e.g., almost all DRC production) (Hoare, 2015). In 2013, illegal logging emitted over 190 million tons of CO_2, more than total emissions from Denmark, Norway and Sweden (Hoare, 2015). Economic impacts are largely revenue losses for states and, in some cases, private forest owners. These hurt livelihoods for forest-dependent people and displacements of people through corrupt land and forest acquisition practices (Pokorny *et al.*, 2016; Tacconi, 2007b). Illegal production of biofuel is large especially in Africa. Most wood pellets and fuelwood in Asia and the Pacific and Latin America are produced legally at medium to large scale, yet in Africa a significant share is associated with small-scale, poor, informal actors (Mohammed *et al.*, 2015). Fuelwood harvesting has the most effects on dry forest, grassland and savannas.

A number of factors have contributed to drive illegal logging, beyond the costs and the returns from sustainable forest management (Pokorny & Pacheco, 2014), including quite poor investment incentives for companies (Contreras-Hermosilla, 2001), poor governance ranging from weak enforcement capacity (Ehara *et al.*, 2018) and over-regulation to corruption including infringements of weak property rights (Alemagi & Kozak, 2010; Cerutti *et al.*, 2013; Contreras-Hermosilla, 2001; Pokorny, 2013; Pokorny *et al.*, 2016; Smith *et al.*, 2003; Tacconi, 2007a). Most of the reported illegal logging is industrial logging in developing countries, yet small scale (artisanal or chainsaw) and on-farm illegal logging has been reported as quite significant in some cases (Cerutti *et al.*, 2013; Hoare, 2015). Its growth is explained by two factors. First, it is the increased timber sourcing from secondary forests, fallows and farms as natural forest concessions move further away with corresponding increases in transport costs. Second, it is the reduction in illegal industrial logging due to improvements in transparency.

Poaching also greatly threatens biodiversity (Clarke & Rolf, 2013) and is rising **(Figure 2.1.14c)** given increasing demands for bushmeat, traditional medicine, souvenirs, pets and luxury goods (Hofer *et al.*, 1996). Poaching has pushed many species to the brink of extinction, even those in the IUCN's list of threatened species, e.g., rhinos and tigers.

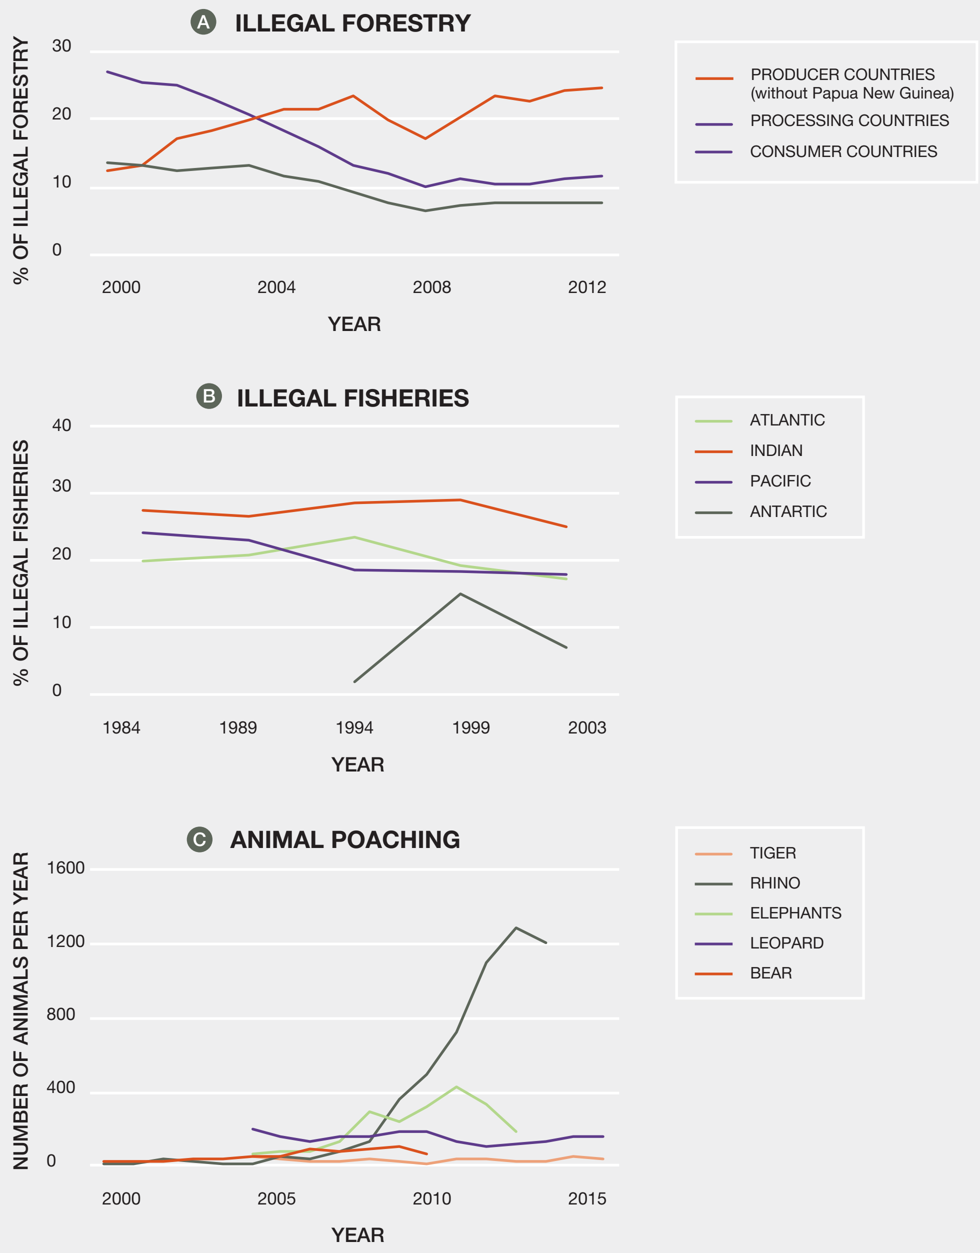

Figure 2 1 14 **Trends in illegal extractions from nature.**

A Producers, processers, and buyers of illegal wood: Percentage of total from 2000 to 2014, B Illegal fisheries: percentage of total fisheries that is illegal by region from 1984 to 2003, C Animal poaching: total number of animals per year from 2000 to 2017. Sources: Illegal forestry: Hoare (2015); Illegal fisheries: Agnew *et al.* (2009); Illegal poaching: data from the Wildlife Protection Society of India (http://www.wpsi-india.org/) for India only (Leopard/Tiger) and from http://www.poachingfacts.com/, reporting for some countries only and considering only years with consistent presence of data (Rhino/Elephant/Bear).

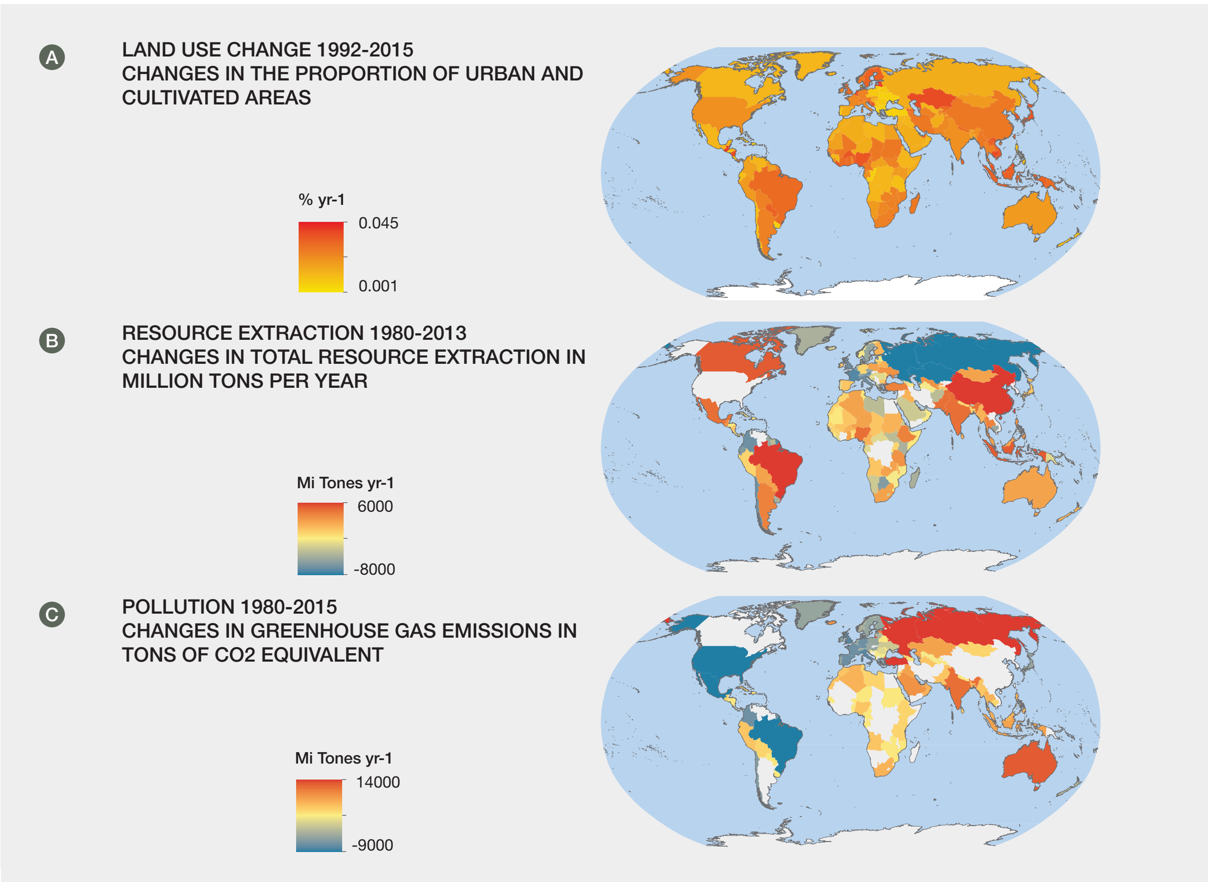
Various international organizations (e.g., WWF, IUCN) and agreements (e.g., CITES) include considerable efforts to eliminate poaching and countries (Kenya, Tanzania, South Africa) have taken drastic measures to control it and punish poachers, e.g., applying 'shoot-on-site' (Messer, 2010). While some of these mechanisms have slightly decreased poaching in many countries, it is still difficult to bust the invisible connections between the poachers and the recipients or users of animal parts.

Poaching has been promoted, to date, by several factors. Corruption, combined with different standards with respect to poaching bans, has greatly weakened law enforcement (Smith *et al.*, 2003). There is a lack of detection of tons of animal parts, or live animals, crossing political boundaries including international borders. Further, poor infrastructure, together with poorly equipped personnel engaged in trying to control poaching in many of the countries where it primarily takes place, reduces timely responses when a poaching incident is reported. But even when policy instruments officially are in place and their implementation is in fact being actively attempted, the lucrative financial gains for poaching driven by the high demand for animal parts and live animals have pushed poachers to discover innovative means of evasion (Knapp, 2012; Lindsey *et al.*, 2013; Milner-Gulland & Leader-Williams, 1992; Warchol & Kapla, 2012).

2.1.12 DIRECT DRIVERS OVERVIEW: AGGREGATING IMPACTS ACROSS SECTORS

Human actions to satisfy needs and goals – as above fisheries, agriculture, logging, harvesting, mining, infrastructure, tourism, transport, restoration – clearly affect nature quite considerably. Their aggregated impacts are classified in IPBES into five categories of direct drivers: land-use / sea-use change; resource extraction; pollution; invasive and alien species; and climate change. Each of these are addressed in independent sections below, with an introductory overview.

Overall temporal trends (**Figure 2.1.12**, maps in **Figure 2.1.15**, Figure S18 for IPBES regions) for the 5 categories of direct drivers show steady increases over the past five decades, across the planet, with differences across trends. Rates of land-use change are lower relative to several decades ago although still accelerating in selected countries, given urbanization, agriculture and grazing. Extraction of living biomass has increased overall, yet while some countries dramatically raised output, others did the opposite as they outsourced their demands. Pollution has diverse patterns. Total greenhouse gas



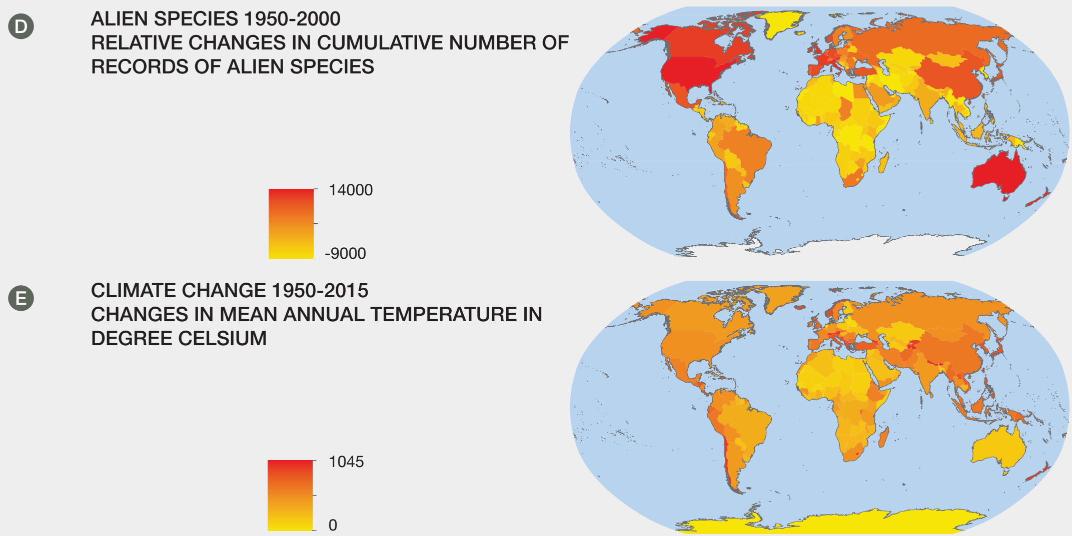


Figure 2 1 15 **Temporal trends per country for direct drivers**

A Land use change: changes in the proportion of urban and cultivated areas within each country calculated using country area data and Global Cover data 1992-2015 (see Chapter 2.2 for further details); B Resource extraction: changes in total resource extraction per year in million tons for 1980-2000, C Pollution: changes in greenhouse gases (CO2, CH4, N2O, CFCs, HFCs, PFCs, SF6, NF3) emissions in tons of CO_2 equivalent for 1980-2015. D Invasive alien species: changes in cumulative number of records of alien species for 1950-2005; E Climate change: changes in mean annual temperature in degree Celsius for 1950-2000 using Chelsa Climate Data. Sources: Hijmans et al. (2005), OECD (2018a), Ritchie & Roser (2018), Seebens *et al.* (2018), World Bank (2018p), WU (2015).

emission has doubled since 1980 (Figure S17, S27) while human-induced warming reached ~1°C (±0.2°C) above pre-industrial levels in 2017 (see section 2.1.17). While air pollution is highest for least developed and lower income countries, important decreases in the rates of emission of greenhouse gas emissions are observed in some of the developed and higher-income countries, due to increased awareness, as well as changes in policies linked to energy sources. Also, the increase is greatest for intermediate – but fastest growing – income levels, developing countries **(Figure 2.1.12)**, where population and income are increasing sharply. Alien species are escalating, especially for developed countries where the arrivals started earliest, and populations are both dense and dynamic. Current cumulative records of alien species are ~40 times larger in developed than in least developed countries. Though comparable across Europe and Central Asia, the Americas and Asia and the Pacific, they are ~4 times lower in Africa (Figure S29). Finally, while climate change is of course a global phenomenon, with global mixing of emissions, some countries are particularly challenged by the fastest rates of changes (see below – and also trends by units of analysis in chapter 2.2 complement this section).

Humanity's footprint has touched 75% of the terrestrial world and much of the oceans (Venter *et al.*, 2016). 25% of the world's terrestrial potential primary productivity has been appropriated largely through cropping and grazing (78% of the appropriation), followed by forestry, the construction of infrastructure, and human-induced fires (22%) (Krausmann *et al.*, 2013). Several biodiversity hotspots have been shown to present very small areas of no or low human footprint, as is the case of Western Australia, Tropical Andes, Northern Cerrado and Central Asian Mountains (Venter *et al.*, 2016). Lowest appropriation values (11–12%) are found in Central Asia, the Russian Federation, and Oceania (including Australia), while the highest ones are found in Southern Asia (63%), as well as Eastern and Southeastern Europe (52%).

A global map of anthropogenic impact on marine ecosystems (Halpern *et al.*, 2008) revealed that by 2007, around 40% of the world's ocean surface was affected by multiple drivers, such as changes in sea temperature, by-catch, habitat transformation, ocean acidification, and ocean pollution. An evaluation of the changes between 2008 and 2013 (Halpern *et al.*, 2015) revealed that more than 65% of the ocean experienced increases in cumulative impact during that period. Globally, increases in climate change related stressors, including sea surface temperature anomalies, ocean acidification and ultraviolet radiation, drove most of the increase in cumulative impact. Yet, impacts from most commercial fishing operations decreased in 70–80% of the ocean (Halpern *et al.*, 2015), confirming previous suggestions (Pauly *et al.*, 2002; Worm *et al.*, 2009) that global catch has stabilized or is declining in most parts of the ocean, and that well-managed fisheries are achieving sustainable yields.

2.1.13 DIRECT DRIVERS: LAND/SEA-USE CHANGES

2.1.13.1 Expansion of agriculture and cities

Over half the Earth's land surface is under cover types of anthropic origin, including agricultural lands, pasture and range lands, and cities (Foley *et al.*, 2005; Hooke *et al.*, 2012). Agricultural expansion is by far the most widespread form of land cover change, with over one third of the terrestrial land surface currently being used for cropping or animal husbandry at the expense of forests, wetlands, prairies and many other natural land cover types (FAO, 2016a; Foley *et al.*, 2005). Population growth (Nelson *et al.*, 2010), followed by urbanization and raising incomes, which are then linked to increasing per capita resource consumption (Liu *et al.*, 2003), clearly are major drivers of deforestation (Lambin & Meyfroidt, 2011).

Over five decades, the largest per cent changes in land use are associated with urban areas (**Figure 2.1.12**, **Figure 2.1.15**, Figure S24). City areas doubled in 1992–2015. The most severe increases were for tropical and subtropical savannas and grasslands, deserts and xeric shrublands, where the urban areas tripled.

Agricultural area increased by over 100 million hectares between 1980 and 2000 across the tropics, half at the expense of intact tropical forests (Gibbs *et al.*, 2010). Pasture for cattle contributed to the largest agricultural land expansion in Latin America, with an increase of ~35 million ha in South America and ~7 million ha in Central America (Gibbs *et al.*, 2010). In 1980–2000, cropland area increased by half in East Africa and a quarter in West Africa, while falling in Central Africa (Gibbs *et al.*, 2010). Africa lost the highest share of tropical forests in the 1980s, 1990s, and early 2000s (IPBES, 2018b). In Southeast Asia tree plantations occupy the largest share of agricultural land, which rose by 7 million ha in 1980–2000, while by the 1990s oil palm was responsible for over 80% of the expansion in tree plantations (Gibbs *et al.*, 2010). Timber extraction and fuelwood collection have also led to forest loss, while opening land for agriculture (Haines-Young, 2009; Hooke *et al.*, 2012). Yet, fuelwood collection is not a main driver, as it is based on collection of dry wood.

Deforestation rates are generally falling, with varying patterns across countries. China has seen high afforestation (FAO, 2015b), due to conservation and restoration over 30 years, in particular since 2000 (Viña *et al.*, 2016). In contrast, despite conservation policies in the 2000s (Macedo *et al.*, 2012; Nepstad *et al.*, 2014), Brazil continues to have significant deforestation (FAO, 2015b).

Other important drivers of the consequential expansion of agriculture – and shift in landscapes – include ongoing shifts toward animal-based diets (Alexander *et al.*, 2015; Rask & Rask, 2011) as well as the collapse of the Soviet Union, which triggered the abandonment of farms and, thereby, recoveries of prairies, woodlands and forests (Alcantara *et al.*, 2012; Bauman *et al.*, 2011; Hostert *et al.*, 2011; Ioffe *et al.*, 2012; Kuemmerle *et al.*, 2008), although some of the latter shifts were followed by a more recent re-cultivation in Southern Russia, Ukraine and Northern Kazakhstan (Meyfroidt *et al.*, 2013).

Following all of this, the global extent of wetlands has declined by 30% between 1970 and 2008 (Dixon *et al.*, 2016), and total loss has been estimated to be as much as 87% (IPBES, 2018a). Losses were greatest in the tropics and sub-tropics, where population growth and agricultural expansion were also highest (UNEP, 2016c). In the last two decades, peatland cover has reduced from 77% to 36% (Miettinen *et al.*, 2012). Peatlands are largely found in South-East Asia, which contains an estimated 56% of all of the tropical peatlands by area (Page *et al.*, 2011).

2.1.13.2 Fragmentation

Land-cover change has increasingly fragmented remaining land cover (see chapter 2.2). Currently, about 20% of the forest areas around the world are close (<100 m) to a forest edge, while 70% are within 1 km (Haddad *et al.*, 2015). Only 20% of tropical areas hold forest areas larger than 500 km^2 (Potapov *et al.*, 2017). The global extent of such areas decreased by 7.2% in the last decade (Potapov *et al.*, 2017), as a result of industrial logging, agricultural expansion, fire, and mining/resource extraction. The certification of logging concessions under responsible management had negligible impact in terms of slowing this fragmentation (Potapov *et al.*, 2017).

2.1.13.3 Landscape/seascape management intensification

Technological advances in agriculture, fisheries, aquaculture, and forestry over the last 50 years (see 2.1.5) led to increases in extraction, yields, and investments (in machinery and inputs), while often increasing the area of influence of these activities (farms or fishing grounds). The IPBES Land Degradation Assessment showed that intensive land use can lead to progressive changes in ecosystem functions and, in cases, irreversible changes then land abandonment (IPBES, 2018a).

Livestock density and herd management are the main causes of rangeland degradation, which can be exacerbated by changes in fire regimes and harvesting

(IPBES, 2018a). Asia has the most rapid grassland change (Akiyama & Kawamura, 2007). Agricultural intensification in regions has been linked to the stabilization or even reductions in agricultural land area, particularly for the sub-Saharan African region (Ausubel *et al.*, 2013; Brink & Eva, 2009; Lambin & Meyfroidt, 2011; Ramankutty *et al.*, 2006; van der Sluis *et al.*, 2016; van Vliet *et al.*, 2015; Wood *et al.*, 2004). When linked to subsistence agricultural production with low soil fertilities, low usage of agrochemicals, and low yields, this has led to reductions for natural land cover types (Brink & Eva, 2009; Wood *et al.*, 2004). Yet, agricultural intensifications have led to increases in yields that have come at the cost of an accelerated pollution of both soils and water (IPBES, 2018a)

2.1.13.4 Land degradation

Land degradation is the reduction or loss of biological or economic productivity and complexity (including soil erosion, deterioration in physical, chemical, biological or economic properties of soils and long-term loss of vegetation) of cropland, rangeland, pastureland forest and woodlands in arid, semi-arid and dry sub-humid areas, that results from land uses or form a combination of processes, including those arising from human activities and habitation patterns (IPBES, 2018a). Degradation is occurring in all land cover, land use and landscape types, in all countries (IPBES, 2018a). Degradation is hard to measure (Herold *et al.*, 2011; Houghton, 2012; IPBES, 2018a; Lambin, 1999), given a paucity of data and the absence of estimates, especially in the tropics (Houghton, 2012). Degradation is driven by multiple drivers including land use change, intensification, pollution, and invasive alien species, many distant from where impacts are felt (IPBES, 2018a). Loss in forests, for example, are linked to uncontrolled logging (Tacconi, 2007b), fires, agricultural expansion (Lawrence, 2005; Van Vliet *et al.*, 2012) and also charcoal (Ahrends *et al.*, 2010; Chidumayo & Gumbo, 2013). Most prominent in Latin America and Asia is timber extraction while, in Africa, it is fuelwood and charcoal (48%) (Hosonuma *et al.*, 2012; Kissinger *et al.*, 2012). Desertification, i.e. land degradation in arid, semi-arid and dry sub-humid areas, is particularly severe for 38% of the world's population, including pastoralists and smallholder farmers tending lands disproportionately vulnerable to degradation (IPBES, 2018a).

Soil degradation includes loss of soil as well as changes in its physical, chemical and biological properties (IPBES, 2018a). Erosion causes nutrient loss (Lal, 2014) and reduction of agricultural productivity, plus flooding, water pollution and sedimentation of reservoirs (Munodawafa, 2007; Rickson, 2014). Erosion may also negatively affect the global carbon, nitrogen and phosphorus cycles (Chen *et al.*, 2010b; Quinton & Catt, 2007). Indeed, soil organic carbon, has fallen globally from land conversion and unsustainable land management practices (IPBES, 2018a). Reliable global estimates of the magnitude and extent of soil erosion are unavailable but its occurrence in all countries can be confirmed (IPBES, 2018a).

Soil acidification is associated with atmospheric deposition of strong acids (acid rain), as a result of emissions of sulfur dioxide and nitrogen oxides exacerbated by anthropogenic activities. Acid deposition on poor soils covered by temperate forests (Driscoll *et al.*, 2001; Greaver *et al.*, 2012), forest and crop harvesting (especially if frequent) (Likens *et al.*, 1998) and loss of nutrients due to rain and irrigation (leaching) (Lawrence *et al.*, 1987) can all exacerbate its effects.

Global soils in over 100 countries are affected by salinity, linked to climate change and increased use of irrigation for production of crops (Squires & Glenn, 2009). Salinity occurs naturally, yet it is often exacerbated by irrigation at rates not adequate to exceed evapotranspiration rates (FAO & ITPS, 2015), by poor drainage or groundwater levels near the soil surface (< 2m), by the use of brackish water to irrigate, by intrusion of seawater near coastal areas, and by shifts from deep rooted perennial vegetation to shallow rooted annual crops and pastures (FAO & ITPS, 2015).

2.1.14 DIRECT DRIVERS: RESOURCE EXTRACTION

2.1.14.1 Rates of extraction of living and nonliving materials from nature

Extraction of living biomass and nonliving materials is increasing as both populations and per capita consumption **(Figure 2.1.4, Figure 2.1.12, Figure 2.1.15)** increased sixfold from 1970 to 2010, while the demand for materials used in construction and industry quadrupled during that time.Materials for construction and industry increased 4-fold, with the most dramatic increases for lower-middle (7-fold) and upper-middle income countries (11-fold) and the Asia and the Pacific region (10-fold for whole region) (Robinson & Bennett, 2004; Schandl & Eisenmenger, 2006; Schandl *et al.*, 2016) and, generally, the growing economies (Figure S18, Figure S25, Figure S26). The use of biomass, fossil fuels, metal ores and non-metallic minerals doubled from 2005 (26.3 billion tons) to 2015 (46.4 billion tons), growing an annual rate of 6.1%.

Yet extraction rates varied widely by country, barely increasing in Africa since 1970 (Schandl *et al.*, 2016). The global shares for Africa, Latin America and the Caribbean, and West Asia were relatively constant over four decades, with all growing in total volume, while Europe and North America fell sharply in terms of their global shares of direct extraction (Schandl *et al.*, 2016). These differences may reflect sectoral shares (see above), as extraction for agriculture, forestry, fishing, hunting only doubled in 50 years but construction and industry rose more (WU, 2015).

Cascading effects of extraction can be manifested as biodiversity losses and accelerated changes in climate (Butchart *et al.*, 2010), most prominently in tropical forests, marine, coastal and polar ecosystems (Bradshaw *et al.*, 2009; Geist & Lambin, 2002). Some types of extraction also result in land-use change, with consequences for biodiversity, soil erosion and degradation, GHG emissions, and potential loss of an array ecosystem services (Geist & Lambin, 2002).

Extraction beyond sustainable levels has consequences for biological dynamics and ecosystem function. Yet assessing what levels of extraction of resources are sustainable is very complex, as species- and context-specific efforts are needed. Impacts of overexploitation can be observed in life histories, genetic patterns of populations, and community and ecosystem functions (Ticktin, 2004). Wildlife extraction through hunting from tropical forests, for instance, is estimated to be well above the sustainable rate (Bradshaw *et al.*, 2009) and for terrestrial species, exploitation (26%) is the second most common threat preceded only by habitat loss (50%) (WWF, 2016).

2.1.14.2 Freshwater withdrawals

Freshwater resources are unevenly distributed. About one third of the Earth's land subsurface is underlain by relatively homogenous aquifers (exclude the Antarctic), often in large sedimentary basins with suitable conditions for groundwater exploitation (WHYMAP & Margat, 2008). Asia (30.72%) harbors most of these aquifers, followed by Africa (28.48%), Central/South America (17.64%), Europe (10.88%), North America (6.78%) and Oceania (5.49%). Most of the largest global aquifer systems are found within Africa (35%), followed by Asia (27%), the Americas (22%), Europe (11%) and Oceania (5%) (Richey *et al.*, 2015; WHYMAP & Margat, 2008).

Global water withdrawals are hard to calculate, as their estimation depends upon reliable data at the local and country level, yet reliable data are limited to a few countries. Estimations by FAO suggest that water withdrawals have risen from less than 600 km^3/year in 1900 to nearly 4,000 km^3/year in 2010, faster than population growth (FAO, 2011c). The surface waters of key river basins such as the Colorado, the Huang-He (Yellow River), the Indus, the Nile, the Syr Darya, and the Amu Darya are heavily used (WRI, 2000) and 21 of 37 aquifers have exceeded their 'sustainability tipping points' during 2003–2013 (Richey *et al.*, 2015). Increased groundwater extraction has been attributed to agricultural use (69%), industrial use (19%) and direct human consumption (12%) (FAO, 2011c; Wada *et al.*, 2014) with growing populations, industries and, more generally, economies (Alcamo *et al.*, 2003; FAO, 2011c; Mekonnen & Hoekstra, 2011).

Depletion of water resources interacts with many biophysical and societal drivers to contribute to negative impacts on nature and societies. Withdrawals, with climate change, lower mean annual run-off across river basins in Asia and America (Haddeland *et al.*, 2014), as well as water quality (Navarro-Ortega *et al.*, 2015). Depletion threatens water and food security, alters hydrological regimes (Arroita *et al.*, 2017), induces land degradation (Dalin *et al.*, 2015), and conflicts (Richey *et al.*, 2015). Threats from excessive extraction are pronounced in arid and semi-arid regions (Haddeland *et al.*, 2014). Irrigated agriculture leads to drastic effects on wetlands and wildlife conservation (Lemly *et al.*, 2000).

Facing scarcities, improved agricultural and water management practices have been developed to reduce water stress. Successful cases involving smallholder farmers have received considerable attention in recent years. In those involving Indigenous Peoples, land and water management have been integrated (Critchley *et al.*, 2008) – suggesting that improvements are possible despite decreasing aggregate resource availability at global scales (Pretty *et al.*, 2000).

2.1.15 DIRECT DRIVERS: POLLUTION

Quantitative assessments of pollution are limited to a few systematically monitored variables – with inconsistent data quantity and quality across countries. The most robust available data are from remote monitoring, including greenhouse gas emissions and the presence of aerosols (i.e., particulate matter). Country data on access to improved sanitation (e.g., municipal waste or use of pesticides or fertilizers) is available (FAO, 2018a, 2018d; OECD, 2018b; Ritchie & Roser, 2018; World Bank, 2018h), although again with varied data quantity and quality. Significant emissions into the atmosphere, water bodies, and terrestrial systems from industrial activities and households remain unquantified. Yet, currently available data on related metrics suggest that the global pollution levels have increased at rates at least comparable to the total population growth.

2.1.15.1 Emissions into the atmosphere

Population growth, economic activity, energy consumption and technology drive anthropogenic greenhouse gas (GHG) emissions – such as carbon dioxide (CO_2), nitrogen oxide (NO_x), and sulphur dioxide (SO_2) – that trap heat in the atmosphere and contribute to global climate change. Emissions from transportation contribute GHGs and conventional air pollutants and particulates (UNEP, 2016e). Smaller particles (PM 2.5) are important threats to human health (WHO, 2016). GHG emissions have risen consistently, combining them with small particles, all countries show increases in air pollution (**Figure 2.1.12**, Figure S27, Figure S28). Largest increases are found in Northern Africa, Central Asia, and East Asia – due to a lack of regulations as well as to geological and climatic factors.

Some countries have sharply increased CO_2 emissions since 1980, while others reduced them (Figure S28). Europe and the Central Asian region reached peak CO_2 emissions in 1990, steadily decreasing since then. The Asia and the Pacific region has surpassed Europe and America to become the largest emitter of CO_2 since 2004. Major CO_2 producing regions are the United States (15%), the European Union (10%) and India (6.5%), which with China account for 61% of the total global emissions (Olivier *et al.*, 2015). CO_2 emissions increased on average (14%) in Latin America and the Caribbean, from 2006 to 2011 (UNEP, 2016d; World Bank, 2017c). During 2000–2010, Africa, Asia and the Pacific, Latin America and North America increased 15% in methane emissions (UNEP, 2016d). Thus, while GHG emissions are driven by economic development, displacement of production and extraction by trade allows for emissions, in some cases, to have fallen for higher incomes while increasing for lower incomes.

The reduction in GHG emissions in developed countries is actually a transference of GHG to developing countries, referred to as "GHG leakage", through international trade, which accounts for ~30% of CO_2 emissions (see also 2.1.6.3.2) (Aichele & Felbermayr, 2015; Kanemoto *et al.*, 2014). In fact, higher-income countries did not actually reduce emissions, but just shifted them. For instance, during the 1990–2011 period, developed countries reduced emissions by 1.59 Gt while developing countries increased emissions by 13.7 Gt. However, after assessing the CO_2 leakage by assigning responsibility to consumers, in 2011 developed countries transferred 2.95 Gt of CO_2 to developing countries through trade (Kanemoto *et al.*, 2014). Developed countries shifted their non-CO_2 GHGs emissions to developing countries even more strongly than they did for CO_2.

Emissions of nitrogen oxides ($NO_{x)}$ are associated with roads transport, energy production, and many commercial, institutional and household activities. NO_x emissions contribute to acid deposition and eutrophication and have drastically increased. Asia, including the Middle East, accounts for ~30% of the global emissions. NO_x emission levels have decreased in the US and in Western Europe, while increasing in Africa over the last decade (Figure S28; EEA, 2014; UNEP, 2016b).

Emissions of SO_2 from the combustion and oxidation of fuels and other materials have risen due to industry and shipping. Asia showed an increasing trend since 2000, contributing 41–52% of global emissions, while emissions from North America and Europe declined from 38% to 25%. SO_2 emission from industry increased from 32% to 38%, while those from international shipping increased from 9% to 25% over the last decade (Klimont *et al.*, 2013) as trade rose.

Emissions of particles into the atmosphere ($PM_{2.5}$ -particles smaller than 2.5 micrometers) are highest in least developed countries **(Figure 2.1.12)** and in high income oil producing countries (Figure S28). Northern Africa has highest $PM_{2.5}$ emissions (De Longueville *et al.*, 2014; Van Donkelaar *et al.*, 2010). Emissions due to residential energy use, such as heating and cooking, are prevalent in India and China. Those from traffic and power are high in the US (Lelieveld *et al.*, 2015).

Higher levels of exposure of human population to air pollution within lower-income countries, especially in Northern Africa and Central Asia, can be attributed to climatic / geological factors (arising from, e.g., dust and storms), predominant energy sources, and agricultural emissions (Lelieveld *et al.*, 2015). Additionally, another important factor is the fact that dirtier phases of industrial processes are exported to lower income countries with reduced regulations and enforcement (see also 2.1.6.3.2).

Other airborne contaminants also have had major impacts on nature and people. Mercury enters the atmosphere from volcanoes, and coal burning, then is transported to areas such as the Artic, with a 10-fold increase in upper-trophic-level mammals such as beluga whales, over the past 150 years (AMAP, 2018). Global emissions of nitrogen from synthetic fertilizers and the expansion of nitrogen-fixing crops are several orders of magnitude larger than pre-industrial levels (Vitousek *et al.*, 1997a).

Noise's effects on nature are increasingly observed. Expansions of human populations, transport networks and extraction have a range of impacts upon species, depending on auditory capacities (Shannon *et al.*, 2016) and noise wavelengths (Todd *et al.*, 2015). Underwater noises that are due to shipping are significant marine pollutants (Williams *et al.*, 2015). Behavioural changes for both individuals and entire ecological communities have been observed in response to a wide range of noise sources and exposure levels (Shannon *et al.*, 2016; Todd *et al.*, 2015; Williams *et al.*, 2015).

2.1.15.2 Contaminants dissolved in/carried by water

Water quality has fallen over the last five decades, with key environmental and societal impacts. Major sources include untreated urban sewage and industrial and agricultural run-off, erosion, airborne pollution, and salinization, as well as oil spills and dumping of substances into the oceans. It is estimated that over 80% of urban and industrial wastewater is released to freshwater systems without adequate treatment, a volume six times as large as that in all of the world's rivers, i.e., 300–400 million tons of contaminants (UN, 2003; UN-Water, 2015; WRI, 2017; WWAP, 2012).

One available indicator on water quality is that of access to improved sanitation facilities which shows very contrasting patterns among countries with different income levels, as 60% of the population in low income countries do not have access to such facilities (World Bank, 2018m). Over 600 million people lack access to safe drinking water, nearly half in Africa, followed by Asia, then Latin America and the Caribbean (WHO-WEDC, 2013). Large regional variance in wastewater treatment includes 70% in Europe but as low as 20% in Latin America (Sato *et al.*, 2013). Untreated urban wastewaters dumped into the environment (Beketov *et al.*, 2013; Malaj *et al.*, 2014; Moschet *et al.*, 2014; Stehle & Schulz, 2015; Van Dijk *et al.*, 2013) contain fecal coliforms, organic pollutants (UNEP, 2016b, 2016c, 2016d, 2016e, 2016f), heavy metals, and pharmaceutical residues (Cleuvers, 2004; Santos *et al.*, 2010; Wilkinson *et al.*, 2016).

About a quarter of the rivers in Latin America, 10–25% in Africa and up to 50% in Asia have severe pathogen pollution, largely caused by untreated wastewater (UNEP, 2016a). More than 200 types of molecules derived from pharmaceutical processes have been measured in natural waters (Pal *et al.*, 2010; Petrie *et al.*, 2015), frequently anti-inflammatory drugs, antiepileptic, contraceptives or antibiotics. These impair organisms in rivers (Brodin *et al.*, 2014) and in estuarine and marine waters (Guler & Ford, 2010; Kidd *et al.*, 2007; UNESCO & HELCOM, 2017). Human health and nature concerns also include chemicals like dissolved metals (zinc, copper, aluminum) or surfactants, whose risks to aquatic ecosystems remain high even within higher-income countries (Johnson *et al.*, 2017).

Agriculture causes most soil erosion and nutrient run-off to freshwaters (Quinton *et al.*, 2010). Fertilizers used in crop production are also drained into continental, coastal and marine water bodies at accelerating rates (Figure S21), with nitrogen fluxes (mainly as nitrate) rising 4- to 20-fold in the last decade (Camargo & Alonso, 2006; Mekonnen *et al.*, 2015). Nutrients from fertilizers in continental water bodies flow into coastal waters, stimulating excessive plant growth and, in extreme conditions, hypoxia or oxygen-depleted "dead zones" plus harmful algal blooms that affect primary and secondary productivity (Altieri *et al.*, 2017). By 2008, 494 coastal dead zones were listed. Pesticides, agricultural insecticides, and newer generation molecules (like pyrethroids and neonicotinoids) (Stehle & Schulz, 2015) reduce macroinvertebrate richness in rivers by up to 40% (Beketov *et al.*, 2013; Van Dijk *et al.*, 2013), while urban and agricultural herbicides exert effects on non-target species like algae (Malaj *et al.*, 2014; Moschet *et al.*, 2014). Ecotoxic chemical micropollutants, including pesticides, pharmaceutical residues, plastics, and dissolved metals all exert chronic effects and have endocrine disruptive properties that affect freshwater biodiversity and jeopardize the health of water ecosystems (Beketov *et al.*, 2013; Malaj *et al.*, 2014; Moschet *et al.*, 2014; Stehle & Schulz, 2015; Van Dijk *et al.*, 2013).

Lower water quality has led to severe changes in the ecohydrology of water systems (Carpenter *et al.*, 2011). In the past decade, the trend of deterioration has shifted from developed to developing countries, with increasing population and economic activity (UNEP, 2016a). The Water Quality Index (WATQI), an index ranging from 0 (worst) to 100 (best) that combines five parameters (pH, dissolved oxygen, total phosphorus, nitrogen concentrations, electrical conductivity) was 69.21 in 2012, globally, with the highest values in Europe (80.38), then Oceania (79.19), the Americas (76.59), Asia (76.59) and Africa (57.74) (Srebotnjak *et al.*, 2012). Climate change, hydrologic flow modification, land-use change, and aquatic invasive species interact with other drivers of water pollution (Carpenter *et al.*, 2011; UNEP, 2016a) to help explain this significant spatial variation.

Marine water quality is strongly affected by oil spills and the dumping of toxic compounds. Oil spills, toxic for marine life and difficult to clean up, are a major contamination source. In 1990, 1.1 million tons of oil was lost via spills. As technologies and policies have improved, by 2015 the magnitude was ~25,000 tons. Yet spills still contribute over 10% of oils entering the oceans (Anderson, 2013). Marine pollution is also affected by dumping and dumping bans (UN, 2017). Authorities are paying more attention to "black" lists of substances that should not be dumped (toxic organohalogen compounds, carcinogenic substances, mercury and cadmium), as well as "grey" lists (e.g. arsenic, lead, copper and zinc and their compounds, organosilicon compounds, cyanides, fluorides and pesticides) (IMO, 1972). In 2003–2012, the total chemicals entering seas rose by 12%, down 60% in North America and Europe but up 50% in the Pacific (UN, 2017).

Emissions of NO_x have acidified freshwater ecosystems (Skjelkvåle *et al.*, 2001; Stoddard *et al.*, 1999). Lakes and streams of eastern North America and Northern and Central Europe are highly acidified, with pH values ranging from 4.5 to

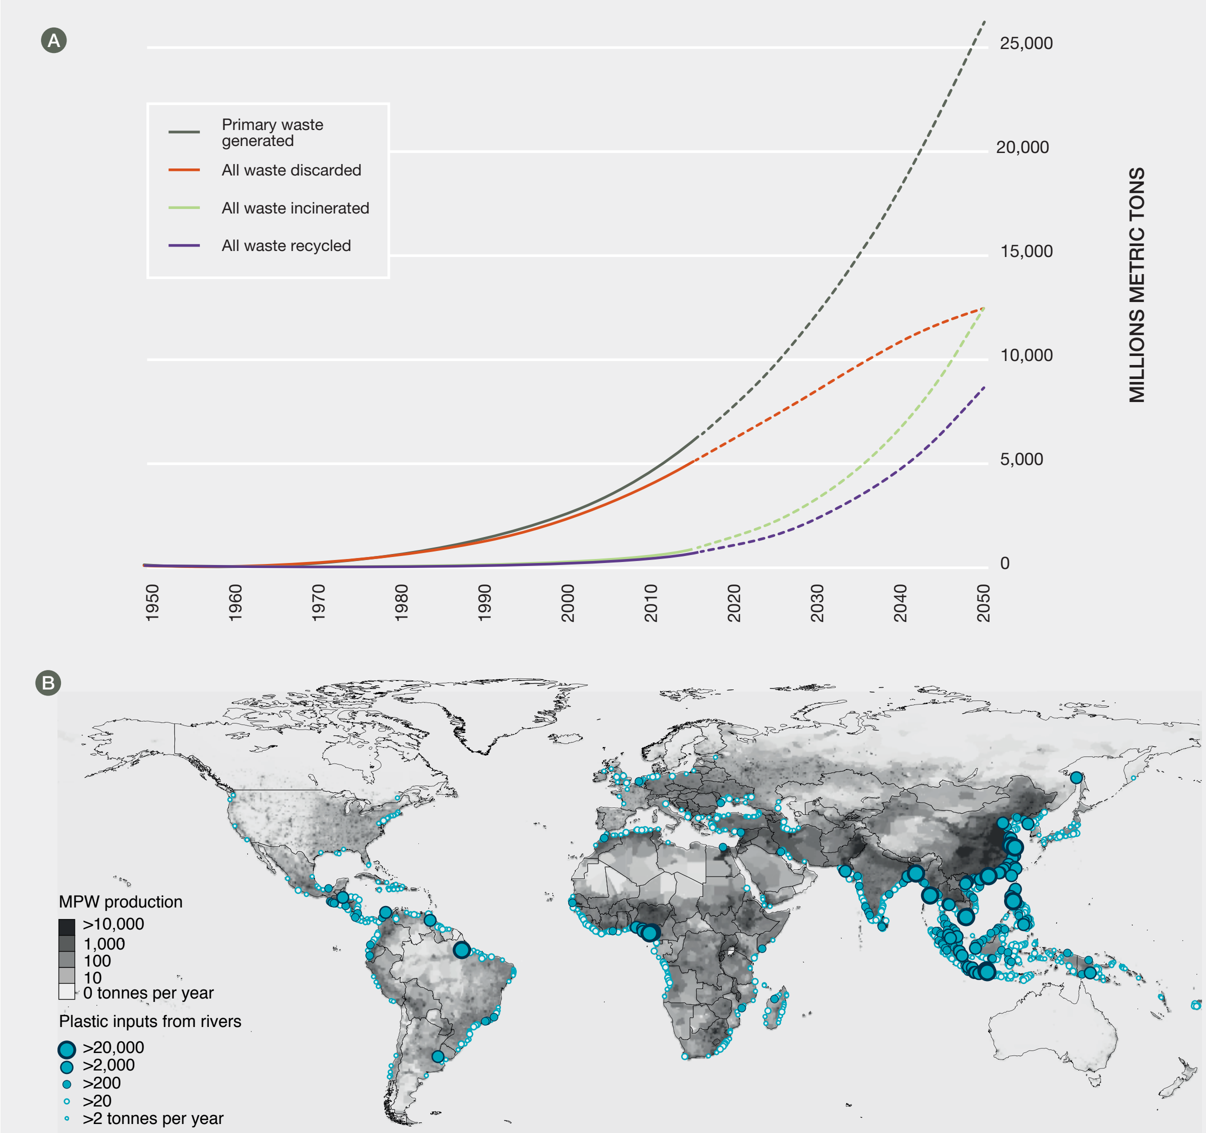

Figure 2 1 16 **Plastic waste production and flow into global oceans.**

A Trend of cumulative plastic waste generation and disposal (1950~2050); B Mass of river plastic flowing into oceans in tonnes per year; river contributions are derived from individual watershed characteristics such as population density, mismanaged plastic waste (MPW) production per country and monthly averaged run-off; the mode is calibrated against river plastic concentration measurements from Europe, Asia, North, and South America. Source: Geyer *et al.* (2017), Lebreton *et al.* (2017).

5.8 (Doka *et al.*, 2003; Skjelkvåle *et al.*, 2001). Further, salinity levels rose nearly one third in Asia, Africa and Latin America between 1990 to 2010. Severe and moderate salinity levels affect one in 10 rivers in these three continents, making it harder for poor farmers to irrigate their crops (UNEP, 2016a).

2.1.15.3 Disposal or deposition of solids

Solid wastes are increasing, globally, although it is uncertain by how much as systematic solid-waste accounting often remains a challenge. Solid waste is mostly generated in and disposed of in cities. Waste is larger in urban areas, correlated with purchasing power (Hoornweg *et al.*, 2013). Cities produce 1.3 billion tons of solid wastes, per year, for instance. Municipal waste per capita has doubled over the last decade (Hoornweg & Bhada-Tata, 2012).

Solid wastes have impacts at different scales. For neighborhoods, ill-managed waste contributes to respiratory ailments, diarrhea and dengue fever, sewage blockages and therefore local floods (Hoornweg & Bhada-Tata, 2012). At the regional and global scales, solid waste emits methane, contributing to climate change, and produces leachates which contaminate the soils and aquifers. Every type of disposal (incinerating, recycling, downcycling) produces adverse environmental impacts, e.g., all of them contribute to GHG emissions in different ways. Solid waste disposal accounts for almost 5% of the total global GHG emissions (Hoornweg & Bhada-Tata, 2012).

Globally, the composition of waste is changing. Waste that is environmentally and economically costly to dispose has been increasing, while organic waste is decreasing. Yet, regional variation is significant. For example, electronic waste composed of both hazardous wastes and strategic metals (rare earth materials), which have to be separated to be properly disposed of or recycled, is the fastest growing type (UNEP, 2012). Electronic waste management is poorly regulated too, accumulating in landfills and often exported to lower-income countries. Recycling by informal sectors has had negative health effects (Ongondo *et al.*, 2011; UNEP, 2012).

Plastic pollution is escalating, and it is accumulating in the oceans at alarming rates **(Figure 2.1.16)**. Global production of plastic resins and fibers rose at an annual rate of 8.4% from 1950 to 2015, over twice as faster as GDP (Geyer *et al.*, 2017). Perhaps 5% ends up in oceans due to inadequate waste management (Jambeck *et al.*, 2015). Globally, 1.15–2.41 million tons of plastic currently flow from riverine systems into oceans every year (Jambeck *et al.*, 2015; Lebreton *et al.*, 2017; UNEP, 2016a). The top 20 polluting rivers were mostly in Asia and accounted for two thirds of global annual input (Lebreton *et al.*, 2017), while the top 122 polluting rivers contributed over 90% of inputs – and are still largely in Asia, with a few in Africa, plus South and Central America, and one in Europe (Lebreton *et al.*, 2017). Besides rivers, plastic wastes enter via mismanagement in coastal regions (Hoornweg & Bhada-Tata, 2012; Jambeck *et al.*, 2015).

On average, every square kilometer of ocean has 63,000 microplastic particles on its surface (Eriksen *et al.*, 2014; Isobe *et al.*, 2015). Much of it is within the five sub-tropical ocean gyres, where ocean currents cycle and gather marine debris. East Asian seas show concentrations 27 times the average, followed by the Caribbean and the Mediterranean (Law *et al.*, 2010). Plastic is also accumulating along the shorelines (UNEP, 2016a). The ratio of plastic to fish by weight in the oceans was 1:5 in 2014 (Ellen MacArthur Foundation, 2013).

Plastic fragments are a particular concern, as they are difficult to remove from the environment and can be ingested (Barnes *et al.*, 2009), affecting at least 267 species including 86% of all marine turtles, 44% of all seabird species, and 43% of all marine mammals (Derraik, 2002; Laist, 1997). This can affect humans through food chains. For instance, 25% of fish sold for human consumption in a Californian market were found to have microplastics debris (Rochman *et al.*, 2015). Beyond macro- and micro-plastics, plus persistent organic pollutants (POPs; Mato *et al.*, 2001), non-indigenous species (Barnes, 2002) and algae linked with red tides (Masó *et al.*, 2003) are transported with plastics (Barnes *et al.*, 2009), while concerns exist about discarded fishing gear (Gilman *et al.*, 2016).

2.1.16 DIRECT DRIVERS: INVASIVE ALIEN SPECIES (IAS)

Nearly one fifth of the Earth's surface is at risk of plant and animal invasions – including many biodiversity hotspots (IPBES, 2018a). Alien species doubled in the last 50 years (**Figure 2.1.12**, **Figure 2.1.15**, Figure S29; chapter 2.2; chapter 3) and threaten native species and ecosystem services (Capinha *et al.*, 2015; Simberloff *et al.*, 2013; Vilà *et al.*, 2010) as well as economies and human health (Kettunen *et al.*, 2009; Pyšek & Richardson, 2010; Vilà *et al.*, 2010).

The cumulative number of alien species that have been recorded is ~40 times greater within the developed than within least developed countries, due in part to trade and population but also to detection capacities (**Figure 2.1.4**, **Figure 2.1.6**, **Figure 2.1.9**, Figure S29) (Seebens *et al.*, 2017, 2018). While the current recorded levels of alien species in Europe and Central Asia, the Americas, and Asia and the Pacific are all similar, levels are lower in Africa. (Figure S29) (Seebens *et al.*, 2017, 2018). The number of alien species recorded is not equivalent to the number of IAS, as no estimates of invasibility are available and that can vary dramatically across alien species.

IAS hotspots are often in developed countries within North America, Europe and Australasia (Dawson *et al.*, 2017). The number of established alien species, and also their rates of invasion, have risen during the last century (Aukema *et al.*, 2010; Blackburn *et al.*, 2015; Lambdon *et al.*, 2008). In addition, the rate of emerging alien species – never encountered before as aliens – is high, with one quarter of first records in 2000–2005. The rate of introduction of new IAS seems higher than ever before and with no signs of slowing (Seebens *et al.*, 2017, 2018).

Major drivers of invasions are expansions of trade networks, higher human mobility, continuous habitat degradation and climate change. The latter exacerbates nitrogen deposition and increases fire frequency (Aukema *et al.*, 2010; Early *et al.*, 2016; IPBES, 2018a; Seebens *et al.*, 2018). The eradication of established IAS is very expensive (IPBES, 2018a; see more in chapter 2.2).

2.1.17 DIRECT DRIVERS: CLIMATE CHANGE

Climate change is currently a major driver of change in nature, with strong direct global impacts, that also affect impacts of other drivers. Unprecedented rises in atmospheric concentrations of GHGs (namely carbon dioxide, methane and nitrous oxide) across at least the last 800,000 years (IPCC, 2014), are extremely likely to have been the dominant cause of observed warming trends worldwide (IPCC, 2014). Natural variations in global temperatures are considered to be low, as compared to such human-induced warming. The latter is growing beyond a threshold that could not have been otherwise exceeded through natural variation (Herring *et al.*, 2016; IPCC, 2014).

Human-induced warming reached ~1°C (±0.2°C) above pre-industrial levels in 2017, with rises of 0.2°C (±0.1°C) per decade (IPCC, 2018)**.** Impacts include thermal stress, coral bleaching, and melting of sea and land ice (IPCC, 2013). The highest velocities in temperature change are found in flat landscapes and at higher latitudes (Loarie *et al.*, 2009). Most land regions are warming faster than the average, most ocean regions slower (UNFCCC, 2015). Evidence of long-term geophysical and biological changes due to warming is now more clear in many parts of the world – such as in the retreat of mountain glaciers, the earlier arrival of spring (Smit *et al.*, 2001), and changes in the phenological responses of vegetation (Root *et al.*, 2003)and in primary productivity (Lucht *et al.*, 2002). Changes in precipitation have also occurred. Areas in tropical regions have exhibited increased precipitation while areas in subtropical regions have exhibited decreased precipitation (Rummukainen, 2012). Precipitation has decreased more drastically in Northern and Central African Countries and Western Asia (Hijmans *et al.*, 2005).

Climate models have assessed impacts of anthropogenic forcing described above on increases in the frequencies and intensities of extreme events (King *et al.*, 2015) – e.g., heat waves, droughts, heavy rainfall, storms and coastal flooding (IPCC, 2018; McBean, 2004; Mitchell *et al.*, 2006) (see chapter 4 for further details). These events result from sporadic weather patterns (Luber & McGeehin, 2008) and they can be intensified by climate variability (e.g., due to El Niño/Southern oscillation) (Cai *et al.*, 2015; L'Heureux *et al.*, 2016; Newman *et al.*, 2018; Weller *et al.*, 2016). The increase in the frequency and intensity of such extreme events has been linked to considerable effects on well-being, with losses of life, injuries, and also other negative health effects, together with damages to property, infrastructure, livelihoods, service provision and environmental resources (UN, 2016c). In particular, important increases in the frequency and intensity of devastating hurricanes have been projected (Bender *et al.*, 2010; Emanuel, 2017; Knutson *et al.*, 2010; Ornes, 2018; Risser & Wehner, 2017).

The effects of all of these changes – temperature, precipitation, and frequency and intensity of extreme weather events – can accumulate and interact for further unexpected nonlinear change, with perhaps irreversible impacts on nature and nature's contributions to people and to society – including economic growth and food and water security (Burke *et al.*, 2015; Franzke, 2014; Friedrich *et al.*, 2016; Hegerl *et al.*, 2011; Schneider, 2004). Climate-driven changes can interact with other direct drivers, at times exacerbating impacts on nature and society (IPBES, 2018b, 2018a). Interactions of climate with other factors could also initiate nonlinear climate responses, yielding more extreme and/or rapid effects of climate change (Mitchell *et al.*, 2006).

2.1.17.1 Sea-Level Rise

From 1901 to 2010, the global sea level rose by 0.19m (0.17 to 0.21m), with an ongoing rate of rise of over 3 mm yr^{-1} across recent decades. This rate of sea-level rise (SLR) is faster than that experienced across the previous two millennia, and is likely to continue or accelerate (Alverson, 2012; IPCC, 2014). The increase in global temperature has a direct linkage with SLR (Church *et al.*, 2006), as SLR results from ocean thermal expansion, with reductions in the glaciers and the Greenland and Antarctic ice sheets (Cazenave & Cozannet, 2014; IPCC, 2014).

SLR is not homogeneous. In 1993–2012, the western Pacific Ocean exhibited a rate of SLR three times higher than the global mean, while much of the west coast of the Americas had a sea level reduction (Cazenave & Llovel, 2010; Stammer *et al.*, 2013). SLR is, in turn, a contributor to climate change acceleration (Galbraith *et al.*, 2002; Goodwin, 2008), and the increased severity of storm-surge events (Church *et al.*, 2008; Nicholls & Cazenave, 2010). Low-lying coastal areas, including many cities, beaches and wetlands are the most vulnerable to flooding and land loss from SLR (Nicholls & Cazenave, 2010; Sallenger *et al.*, 2012), with the total threats being the highest in densely populated areas (Stammer *et al.*, 2013). For instance, most countries in South, Southeast, and East Asia are highly vulnerable to SLR because of the widespread occurrence within those regions of very densely populated deltas, while a number of countries in Africa are highly threatened due to low levels of development combined with rapid population growth rates in coastal areas (Nicholls & Cazenave, 2010).

2.1.17.2 Ocean Acidification

Ocean acidification also drives loss in coastal and marine ecosystem services. In most cases, it is generated by anthropogenic CO_2 emissions (Doney *et al.*, 2009). Acidification results in biochemical alteration of salt water ocean ecosystems (Doney *et al.*, 2009). Current acidity is estimated to be the highest since the extinction of dinosaurs 65 million years ago, above levels experienced at least over 800,000 years (Lüthi *et al.*, 2008). Acidification is most critical for the shallow-water areas over-saturated with calcium carbonate. The highest concentrations of anthropogenic CO_2 are in near-surface waters, as mixing of these waters into the deeper oceans can take centuries. About 30% of the anthropogenic CO_2 is at depths shallower than 200 m, while nearly 50% is at depths shallower than 400 m (Feely *et al.*, 2004). The pH has fallen more than 30% since the industrial revolution, with a massive threat to marine biodiversity (Hoegh-Guldberg & Bruno, 2010). Highest concentrations of anthropogenic carbon in the oceans are in the North Pacific (3.2 Pg C) and the Indian Ocean (3 Pg C). If current rates of GHG emissions are not mitigated, oceans will be vastly different places by the mid-to-late 21st century (Gattuso *et al.*, 2015).

Ocean acidification negatively affects marine organisms and function, which in turn feedback to climate change. Acidification hinders the ability of calcifying organisms to build and maintain their calcium carbonate skeletons and shells, along with creating changes in other fundamental metabolic processes. Acidification also leads to increased phytoplankton production of dimethyl sulfide (DMS) (Gypens & Borges, 2014; Six *et al.*, 2013), which contributes to warming of the Earth's temperature due to a reduction in the reflection of solar radiation. Coral bleaching may also result from ocean acidification, although complex impacts upon the multiple trophic layers are hard to evaluate and predict (Hattich *et al.*, 2017; Kroeker *et al.*, 2010).

Impacts of increasing CO_2 upon the total Net Primary Production of marine systems and, thus, decreasing carbonate concentrations in the oceans and the atmosphere remain largely unknown. A global analysis reports that ~97% of reef areas exhibited warming trends, from 1985 to 2012. Coral bleaching incidents over the last two decades have been more frequent and more severe (Heron *et al.*, 2016). Summarizing, ocean acidification has been affecting fundamental physiological and ecological processes of organisms (Hoegh-Guldberg & Bruno, 2010; Pörtner *et al.*, 2014), leading to changes in the structure of marine ecosystems that underpin risks and vulnerabilities to food and income security (Hoegh-Guldberg *et al.*, 2017). Thus, the impacts of ocean acidification have a direct consequence for societies, including changes in national economies (Busch *et al.*, 2015; Robinson *et al.*, 2010).

2.1.18 PAST PATHWAYS: INCREASING CONNECTIVITY AND FEEDBACKS

Over 50 years, societies and nature have dramatically changed due to many complex interactions among the indirect drivers, among the direct drivers, and between the indirect and direct drivers. With a variety of impacts on nature, and nature's contribution to people, these interactions shape well-being for societies, and its evolution, including through governance motivations and choices.

As a result of increasing global connections, local impacts on nature and people are influenced by interactions at long distances, in some cases with significant time lags and with cumulative effects. The social-ecological changes from these accumulating interactions, from local to global levels, can occur in highly unpredictable ways due to varied conditions characteristic of complex systems, including: nonlinear processes underlying the outcomes; interdependence between distant places; changes with cascading effects; and both positive and negative feedback loops that can exacerbate or reduce the impact of changes on nature and people. All of this greatly affects future trajectories.

Below, we consider a few of the interactions and iterations that have such influences, starting with an illustration of varied correlations among indirect and direct drivers. With variations, by context, each indirect driver that we described can have both immediate and more distant causal impacts upon any number of actions that directly affect nature and, thereby, influences upon direct drivers.

2.1.18.1 Illustrating interconnections

Complex interactions and resulting interconnections between indirect and direct drivers may be partially summarized using statistical tools **(Figure 2.1.17)**. This does not sort out causal links involved, yet it does raise various questions about exactly how these specific correlations have come about.

The direct drivers – land/seascape change, resource extraction, pollution, invasive alien species (climate change was not included as it operates at very different spatial and temporal scales) – strongly correlate with multiple indirect drivers, in terms of the current levels for the indicators measured for each of the different countries **(Figure 2.1.17a)**. In particular, direct drivers correlate with total population, which also correlates with changes in nature (Biodiversity Intactness Index) and environmental footprint. Economic and lifestyle drivers (e.g., gross domestic product per capita, and domestic material consumption per capita) are also correlated with most of the direct drivers, nature and footprint indicators. Functioning institutions and governance (e.g., protection of key biodiversity areas, the absence of conflict) are correlated with some indicators of direct drivers, nature and footprint, though the processes involved are complex and cannot easily be identified from these correlations. Differences across IPBES regions are suggested for some direct drivers.

Looking at country variations in rates of change (1990–2010, **Figure 2.1.17b**), instead of levels variations, again the direct drivers were quite correlated with demographic, economic and lifestyle drivers, confirming the above observed patterns, and additional suggestive correlations were also found. Rates of change in urban populations were correlated with land-use changes, highlighting the indirect effects of urbanization. Human migration was correlated with increases in alien species, highlighting the roles of increased movements of people and goods on these non-native species. In addition, merchandise-export values were correlated with amounts of resources extracted, confirming paramount roles of trade in extraction of living and nonliving materials from nature. These broad patterns support more detailed assertions above and pose future research questions.

Related research is growing. Social–ecological literature has seen an exponential development in the last 15 years **(Figure 2.1.18)**, with a great deal of research on some actions (e.g., agriculture) with direct impacts on nature, plus how they link to climate change, land/sea-use change and economic and governance drivers. While such a map also cannot communicate causal links, as it does not reflect the content of the analyzed papers but rather the frequency of occurrence of terms linked to any of the indirect and direct drivers, it highlights research gaps. For instance, less was found on invasive and alien species, values, or trade-offs and inequalities.

2.1.18.2 Evolving economic and environmental interactions

2.1.18.2.1 Growing globalization

The world is ever more global, leading the environmental footprints of consuming nations to be spread ever farther from where the consumption occurs. Networks across continents, including flows of people, information, ideas, capital and goods, have been growing in the last decades at similar rates for all countries, while being clearly higher for the high income countries **(Figure 2.1.4)**. As a result, the footprint of nations is also growing globally, i.e., fractions of the total land use change, due to consumption, that occurred outside country boundaries have increased **(Figure 2.1.19)**. While high income countries were exporting a large fraction of their footprint even before 1990, even the poorest countries now have a large fraction of their footprints beyond their boundaries.

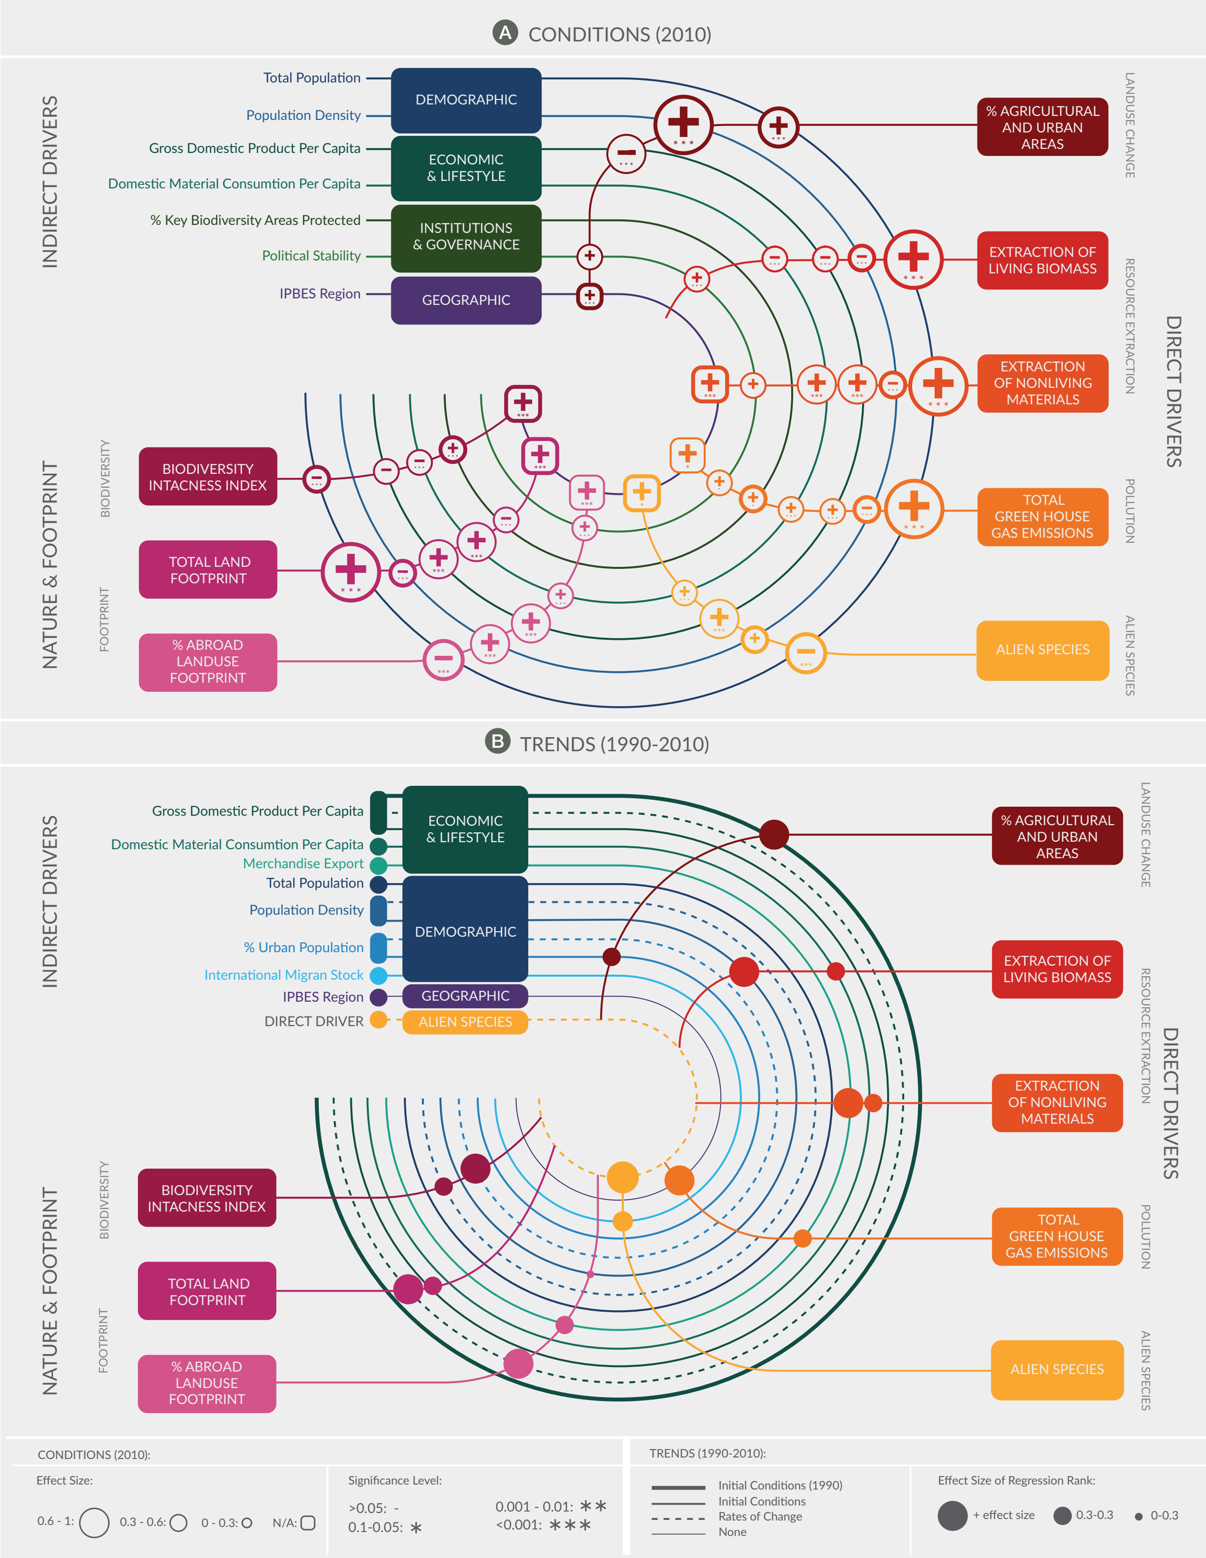

Figure 2 1 17 **Correlations between indirect drivers and direct drivers, as well as indicators of nature and footprint.**

A Correlations between current conditions of countries, (2010). B Correlations between trends of change in country values for 1990-2010. Multiple regression analysis was used as a way of summarizing correlations for current conditions, while regression trees were used for the correlations of the trends. Data used for correlations are by country. Corresponding average trends for development level categories are shown in Figures 2.1.4 and 2.1.12.

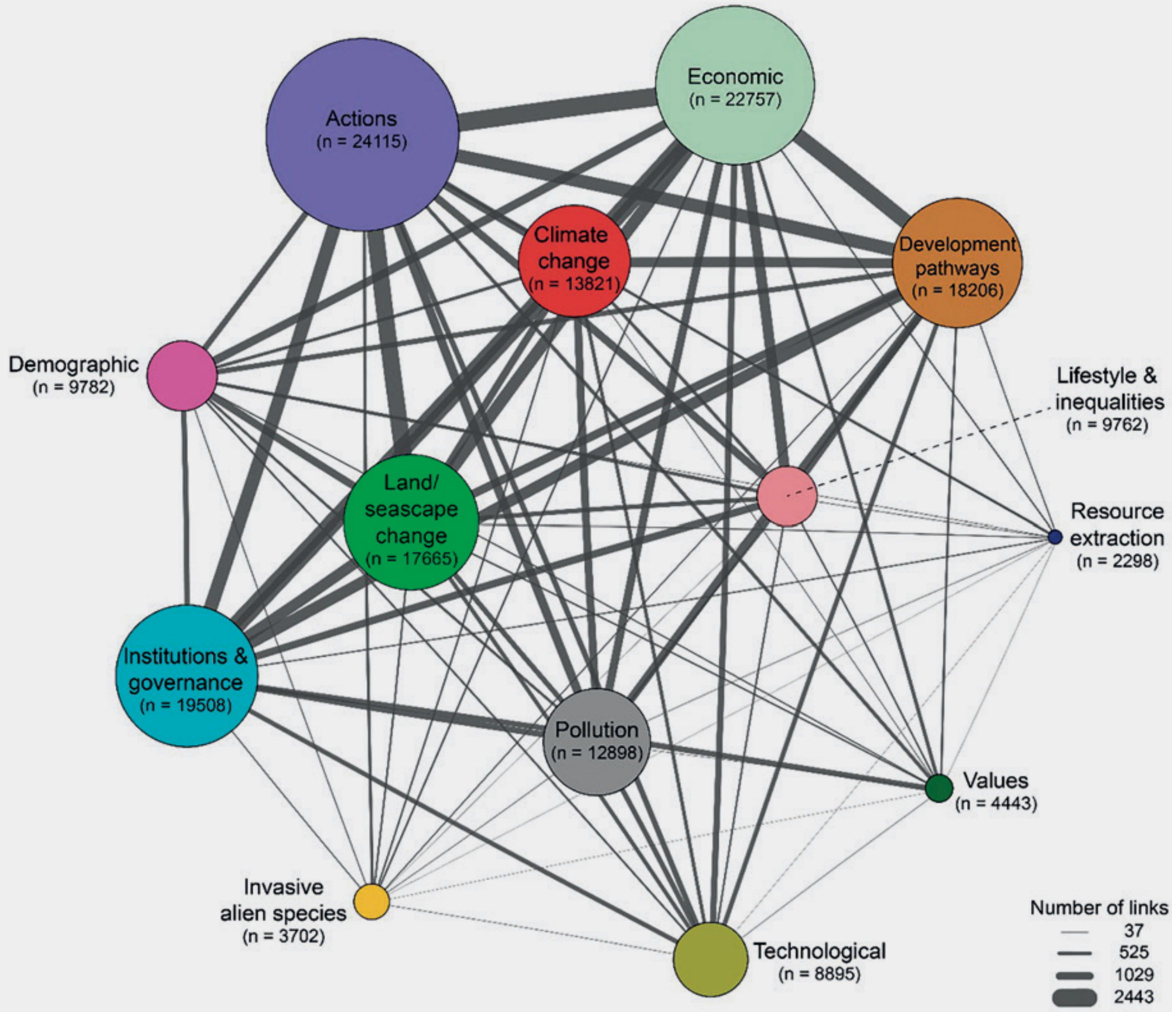

Figure 2 1 18 **Current state of knowledge on interactions among drivers from a systematic literature review.**

The number of papers that address each of the topics (circles) and that address two of them of (lines) are depicted. The literature surveyed was identified using keywords extracted from the Second Order Draft of this chapter, and using the bibliometrix R package, following Mazor *et al.* (2018) Sources: www.webofknowledge.com; www.bibliometrix.org.

2.1.18.2.2 Spreading spillovers

Spillovers from responses to environmental policies – even across borders – can undermine net impacts of governance efforts (see, for example, the case of palm oil, within **Box 2.1.4** below). Understanding and taking into account spillovers is important for evaluations, and for planning. Conservation efforts have expanded: legal limits, including protected areas and other restrictions; as well as positive incentives intended to discourage the degradation of nature (Chape *et al.*, 2005; Jenkins & Joppa, 2009), such as many programs using payments as compensation for protecting and restoring ecosystems (Albers & Grinspoon, 1997; Chen *et al.*, 2009; Daily & Matson, 2008; Uphoff & Langholz, 1998). Yet spillovers from these efforts, nearby or distant, are far from being understood and seldom taken into account (Meyfroidt *et al.*, 2018).

Responses to governance efforts across space and over time can hurt or help policies' objectives – environmental and economic. PAs, for instance, might not change land-use but just displace it (Hansen & DeFries, 2007), raising deforestation elsewhere (Robalino *et al.*, 2017 for local context and heterogeneous impact) while potentially also lowering local wages (Robalino, 2007). Yet context matters: with tourism, wages may rise (Robalino & Villalobos, 2015); and in cases, PAs lower deforestation nearby (Herrera Garcia, 2015) – including by dissuading local investments in economic development (Herrera Garcia, 2015). That

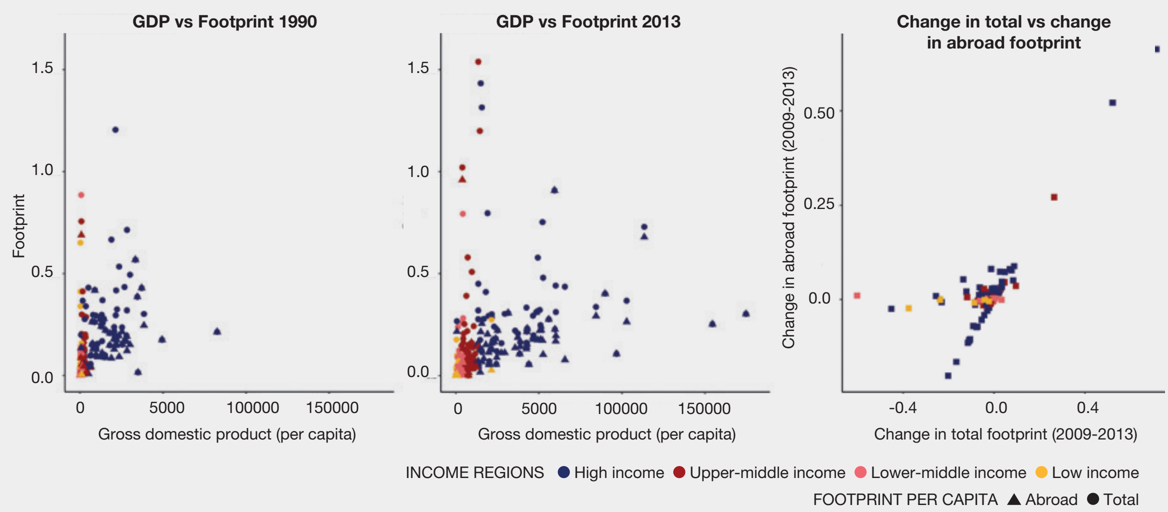

Figure 2 1 19 **Increasing total footprint of nations and exports of footprint: 1990-2013.**

Data shown is the footprint of individual countries, which is the sum of all land uses that occurs around the world to ultimately serve that specific nation's consumption. This land use footprint usually has a portion that occurs within the nation's own border (domestic), and a portion that occurs in within the borders of other countries (triangles), and the sum of these two components form the total footprint (circles). Countries are colored using World Bank's income categories. (Source: own calculations using Eora database, https://worldmrio.com/). The population and GDP data that were used for normalising the results were obtained from the Food and Agriculture Organization of the United Nations (FAO, 2016a; Wiedmann *et al.*, 2015).

may involve deforestation in other regions, if there exist broader spatial spillovers (DeFries *et al.*, 2010; Lambin & Meyfroidt, 2011; Rudel *et al.*, 2009b; Viña *et al.*, 2016; Zhu & Feng, 2003).

Understanding spillovers is essential to formulate policies. While there are studies of displacing land use (Lambin & Meyfroidt, 2011; Meyfroidt & Lambin, 2009; Pfaff & Walker, 2010) and deforestation (DeFries *et al.*, 2010; Liu *et al.*, 2012; Meyfroidt & Lambin, 2009; Verburg *et al.*, 2002; Wassenaar *et al.*, 2007), in policy formulation the consideration of human-nature interactions across spaces often is lacking. That could involve global scales, if prices rise in distant markets when one country lowers logging effort (Sedjo & Sohngen, 2000). Alternatively, it could be local, e.g., reduced motivations to conserve, for those who conserved voluntarily, if external interventions are perceived as a public overreach (Cardenas *et al.*, 2000).

Different spillover mechanisms yield different outcomes (Pfaff & Robalino, 2017). If PES for afforestation leads neighbors to learn that afforestation raises private profits, then others might start such practices in other locations – while those now receiving PES may continue practices after PES (Pagiola *et al.*, 2016 for Latin America). Such spatial and temporal spillovers benefit nature. Another potential spillover mechanism is that private or public conservation actions change the relative net benefits of conservation nearby. While Robalino & Pfaff (2012) find deforestation yields more private deforestation by neighbors, with tourism this can imply that conservation of nature yields neighboring conservation via local incentives to keep forest (Robalino *et al.*, 2017).

Moving to natural resources, many middle income countries possess stocks of oil and for some non-OECD high income countries, fossil fuels constitute a large share of their wealth. In such settings, discoveries can have spillovers through local incomes (Lange *et al.*, 2018b, p. 98) and prices. They can also bring 'the resource curse' (Barma *et al.*, 2012; van der Ploeg, 2011): although some resource-rich countries benefit from their natural wealth, in other countries it has been associated with bad macroeconomic performance and growing inequality among its citizens, with negative effects on other sectors of the economy due to concentrated growth. Further, as fossil fuels are nonrenewable, their extraction has effects upon the future.

Spillovers also imply gains from integration in the planning of development and conservation, for instance as related to transport investments. Consider a leading development policy, roads, and a leading conservation policy, protected areas. Roads increase profits in agriculture and, thereby, pressures for deforestation. That raises the impacts from well-implemented PAs (Pfaff *et al.*, 2016, 2009). Successful protection, in which PAs block the pressures, can in turn have positive spillovers through both agencies' interactions and private responses, as strong PA signals may lower expectations about economic prospects within any region. That has yielded reduced roads investments and in-migration (Herrera Garcia, 2015). Optimal policies could

Box 2 1 4 Palm oil illustrates multiple forms of interaction across national borders.

Palm oil production doubled in 2006-2016 to a global economic value of USD 65.7 billion in 2015. Demands in food (frying and cooking oils, baking fats, margarines, animal feed, confectionery filling, coffee whiteners, ice creams), oleo-chemicals (soaps, detergents, greases, lubricants and candle), fatty acids (to produce pharmaceuticals, water-treatment products and bactericides), and energy (biodiesel) fueled this increase, all encouraged by international capital (Borras Jr *et al.*, 2016) as well as the World Bank (Deininger *et al.*, 2011) and UNEP (Segura-Moran, 2011). States involved envision jobs and revenues to help mitigate high unemployment and to help supplement declining revenues, given falling commodity prices.

About 80% of production is in Indonesia and Malaysia – with the rest across Latin America and West Africa, e.g., growing in Cameroon (Hoyle & Levang, 2012) and Gabon (FAO, 2016a) – and consumption is highest in India, Indonesia, EU, China, Pakistan, Nigeria, Thailand, Bangladesh and USA. This generates tropical deforestation (Borras Jr *et al.*, 2011; Gibbs *et al.*, 2010), reduces soil fertility, raises water and air pollution (through fires) and biodiversity loss, pollutes with pesticides, and blocks communities from soil and water for livelihoods (Edwards *et al.*, 2010; Koh *et al.*, 2011; Temper *et al.*, 2015), while increasing human infections and premature deaths (Burrows, 2016; Fornace *et al.*, 2016).

In response to this, the EU voted to ban palm oil-based biofuels by 2021, while the Roundtable for Sustainable Palm Oil (RSPO) platform of principles, criteria, indicators and certification is followed voluntarily in Indonesia and Malaysia. RSPO has certified ~12 million metric tons (19% of output) with members in 91 countries and Indonesia proposed a Peatland Restoration Agency for 2 million ha, froze concessions, and started to work closely with large consumers.

Yet major plantation companies are shifting investments to Africa, where local values, nutrition, culture and markets in Congo Basin countries are disrupted as doubled prices fuel investment in medium-sized (5-50 ha) plantations in forested areas (Yemefack *et al.*, 2005). This growth has been linked to 'land grabbing' – both there and in the Guinea forest ecosystem, where several land acquisition deals by multinationals are reported (see www.landmatrix.org).

Consciously managing for multiple objectives, is important. One option is further agroecology. Agroforestry has potential for increasing productivity (and profit) and maintaining or enhancing ecosystem services. This requires multiple forms of support, including monetary incentives, technical training and other investment (Minang, 2018) to enhance the ability to manage land.

build from such non-cooperative interactions to pursue the coordination of roads and protection.

Similarly, concessions are a leading development policy in forests, awarding extraction rights. That alone can create incentives for private firms to defend forest assets from illegal invasions. Further, such a strong defense of rights may be a necessary condition for adding conservation influences of global consumer preferences as expressed through certifications (Rico *et al.*, 2017). Thus, further coordination across agencies could optimally locate concessions and protections. Protection also interacts with investment in hydropower, which has led to eliminations of PAs ('PADDD') but could be better coordinated to achieve multiple objectives (Tesfaw *et al.*, 2018).

2.1.18.2.3 Causing conflicts

Social instability is at the heart of environmental, social, economic or geopolitical threats (World Economic Forum, 2017, 2018) (see Figures S31–33). More than 2,500 conflicts over fossil fuels, water, food and land are currently occurring across the planet (including at least 1,000 environmental activists and journalists killed between 2002 and 2013. A report by the NGO Global Witness argues that 913 citizens were killed in their attempt to protect the environment between 2002 and 2013; and that the rate of such killing has been increasing (Global Witness, 2014).

While violent conflict may be decreasing (Lacina & Gleditsch, 2005), conflicts that destabilize social systems can have adverse environmental impacts, which in turn may cause or affect conflicts. Resource scarcities and/or unequal appropriations have triggered conflicts over fossil fuels, water, food, and land. Those conflicts undermine governance, in turn generating further shifts in threats to ecosystems in a harmful social-ecosystem feedback loop.

Links between resource scarcity and conflicts are not clearly established (Bernauer *et al.*, 2012; Koubi *et al.*, 2013), but clear examples, such as the role played by water scarcity in triggering violence in Syria, are available today. Water scarcity is exacerbated by contamination of local sources, the appropriation of water by agriculture, changes within land rights, food insecurity, unemployment, and political instability (Gleick, 2014). Civil conflicts in areas where valuable natural resources are found have tended to last longer, as the access to natural resources creates an economic incentive for armed groups (Lujala, 2010). The control of natural resources (timber, gems or oil) and the revenues from resources finance and motivate conflicts (Le Billon, 2001).

Disputes over use rights relevant for nature can trigger violence and destruction, particularly with weak governance (Brown & Keating, 2015). Violent conflict further disrupts institutions, causing insecurities and distrust (Miteva *et al.*, 2017). For centuries, resources have been linked to warfare

(Feldt, 2007). Matthew *et al.* (2009) suggest that 40–60% of civil wars in the past 60 years were triggered, funded or sustained by natural resources. Renner (2002) highlights that legal or illegal resource exploitation helped trigger, exacerbate or finance ongoing violent conflicts about the control of sites rich in valuable commodities or the points they pass through going to markets. Schaffartzik *et al.* (2016)) document that growing metals demand has generated incentives for countries to seek revenue through exploiting natural resources and exporting primary commodities, with the expansion of extraction frontiers generating conflicts. Billions of dollars can then go to unscrupulous actors.

Controlling natural resources is part of state-based and civil conflicts and an element within the repression of riots and even assassination of activists (Global Witness, 2014). Food riots also rise if food prices rise from physical or constructed scarcities (Lagi *et al.*, 2011). Such violence – including assassinations – can occur if communities are pushed off their lands or threatened by the degradation of their natural resources (Schoenberger & Beban, 2018). Violence might also be used to discourage resistance to large-scale degradation (Blake & Barney, 2018). More generally, conflict can be one symptom of an unequal distribution (Downey *et al.*, 2010) and can affect conservation as more untouched ecosystems harbor groups targeted by military operations (DeWeerdt, 2008). Looking out over time, armed conflict can lead to the withdrawal of financial aid, which is rarely reinstated after a conflict (Glew & Hudson, 2007).

In Indonesia ~20 million people have been affected by forest conflicts (Dhiaulhaq *et al.*, 2015) and the Environmental Justice Organizations, Liabilities and Trade (or EJOLT, www.ejolt.org) documents almost 2000 active environmental conflicts (see **Figure 2.1.20**) – most related to land, minerals, water access and dams (Giordano *et al.*, 2005; Martinez-Alier *et al.*, 2016; Seter *et al.*, 2016) – while the Latin American Observatory of Mining Conflicts

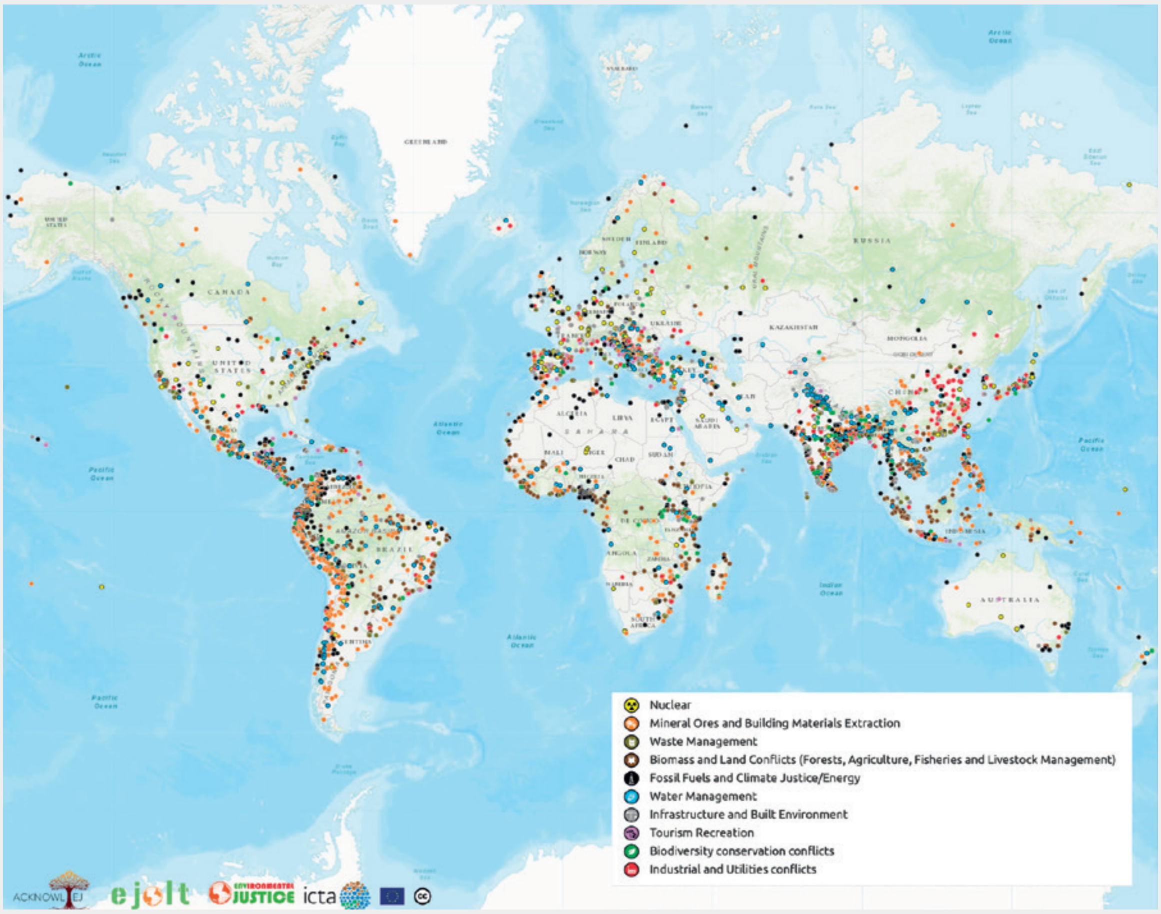

Figure 2 1 20 **Global map of environmental conflicts.**

The environmental justice atlas documents and catalogues social conflict around environmental issues, collecting the struggles of world communities to defend their land, air, water, forests and their livelihoods from damaging projects and extractive activities with heavy environmental and social impacts from around the world. Source: https://ejatlas.org/.

(www.conflictosmineros.net) notes over 150 active mining conflicts, most started in the 2000s after investments in mining in the 1990s (Urkidi & Walter, 2011; Walter, 2017). Butterman & Amey III (2005) suggest underlying international policy spillovers, i.e., that investment shifted due to environmental and labor regulations in Canada, and in the US, as well as due to political instabilities within the former Soviet Union, Asia and Africa. Some of the complex interactions involved in many such conflicts can be illustrated using the Nile Basin's example **(Box 2.1.5)**.

2.1.18.3 Evolving economic and environmental trade-offs

Across the globe, gains and burdens from nature are unequal for different sectors of society – and the trade-offs have evolved for all parties. For example, while a few firms are responsible for much of the fish harvesting around the globe (Österblom *et al.*, 2015), and a few countries are responsible for most of the carbon emissions (IPCC, 2013; Peters *et al.*, 2015), those who are most impacted by the consequences often are other groups that can include orders of magnitude more people with considerably less influence. In fisheries, FAO reports that 34 million people derive their livelihoods through fishing, while over 3 billion people get at least 15% of their protein intake from fish, especially in poor nations (FAO, 2014). Major ecological collapses have impacts upon international seafood market prices in markets (Smith *et al.*, 2017), but also upon the many small fish farmers and many consumers.

Environmental quality studies (Bowen *et al.*, 1995; Morello-Frosch *et al.*, 2001; Pastor *et al.*, 2002) find inequities can result from race and class barriers (e.g., **Box 2.1.3** above as well as **Box 2.1.6** above for including gender). In India, for instance, castes generate an important element of disproportionate pollution and other environmental stressors (Demaria, 2010; Parajuli, 1996). Tribal affiliation often counts in struggles against resource extraction processes, as in the case of Nigeria and other countries in which companies have shifted social and environmental costs of oil extraction onto Indigenous and poor local communities (Martinez-Alier *et al.*, 2014).

These inequalities have serious health consequences. A quarter of deaths and years of life lost are attributed to environmental degradation (Figure S31), with the highest fraction in low and middle income countries (WHO, 2016) given chemical or biological pollution of air, water and soil via agriculture, irrigation, and sanitation. Poor, rural communities are disproportionately affected (WRI, 2017). Negative effects of extreme events affect vulnerable communities in developing countries, who are least able to cope with the risks (Smit & Wandel, 2006), including of climate change (Mirza, 2003) and a likely multitude of primary and secondary effects (Adger, 2003).

Climate change, e.g., a 3°C warming with a 3% loss of GDP, will likely exacerbate inequalities (Mendelsohn *et al.*, 2000; Nordhaus & Boyer, 2000; Tol, 2002). Countries with higher initial temperatures, greater climate change levels, and lower levels of development, which often implies greater dependence on climate-sensitive sectors and in particular agriculture, are expected to bear the highest levels of impacts (Golden *et al.*, 2016, 2017; Marlier *et al.*, 2015; Myers *et al.*, 2014; Vittor *et al.*, 2006; Whitmee *et al.*, 2015).

More generally, losses of natural capital are unequally distributed across countries and regions (**Figure 2.1.21**, Lange *et al.*, 2018a). Further, these inequalities arise within countries as well, including along gender-based and race-based and income-based dimensions within developed countries.

Box 2 1 5 Nile basin's water allocation conflicts, with equity and efficiency considerations.

The Nile basin provides examples of conflicts concerning water allocation at the national scale, i.e., between nations, within an enormous region. This basin covers over 3 million km^2 with an annual discharge of 84 billion m^3 which supports over 200 million people within 10 countries: Burundi, Democratic Republic of Congo, Egypt, Ethiopia, Kenya, Rwanda, Tanzania, South Sudan, The Sudan and Uganda. About 86% of the water from the Blue Nile originates from Lake Tana, which is within Ethiopia. Yet downstream 97% of the water needs in Egypt are fulfilled by the Nile, setting up potential tensions concerning the management of agroecosystems upstream.

Thus, not surprisingly, the decision by Ethiopia to build the Grand Renaissance Dam, which is now under construction, has created conflict with Egypt. Egypt says that the dam will reduce the flows to the lower Nile and that it will lose almost 3 billion m^3 to evaporation. Ethiopia responds that Egypt is losing 12 billion m^3 via the Aswan Dam, which is in Egypt (Di Nunzio, 2013).

The region is rising in population and is modifying agroecosystems to meet needs for food, fuel and fiber. Given rising demand and its impacts on biodiversity, water resources and ecosystems, in order to work out rights structures for both sustainable management and fair utilization the Nile Basin Initiative was established in 1999 with support from each of the ten related countries. Only coordination can ensure sustainability for so many people and ecosystems (Swain, 2002).

Box 2 1 6 Scale, gender, and ecosystem-based differences for trade-offs within fisheries.

At the turn of the century, industrial fisheries and small-scale fisheries (SSFs) (Vásquez-León & McGuire, 1993) disagreed about inequitable relations including competition (Lawson, 1977; Vásquez-León & McGuire, 1993), preferential treatment by the state of the industrial fisheries (Panayotou, 1980; Pauly, 1997), access to specific fishing grounds (Begossi, 1995) and gear (Sunderlin & Gorospe, 1997). Conflict arose between fisheries, conservation and tourism (White & Palaganas, 1991) as well. SSFs were seen at odds with nonconsumptive uses of marine resources (Basurto *et al.*, 2017; Newman *et al.*, 2018). Agencies adopting mandates of conservation and protection were seen as against SSFs (Breton *et al.*, 1996). The conflicts were especially salient around endangered species and charismatic megafauna (Kalland, 1993). Jobs were said to be replaced in tourism and 'green' services yet fishers were skeptical (Young, 1999).

The literature has relied on technology to differentiate SSFs, often with unintended consequences (Basurto *et al.*, 2017). Definitions stress technical capacities, e.g., boat lengths, horsepower, and gear (Chuenpagdee *et al.*, 2006; FAO, 2009c; Smith *et al.*, 2017), excluding some SSF activities. To start, catching fish at sea is a predominately male activity (FAO, 2016b), while women play large roles in shore-side SSF efforts such as procuring ice, bait, food and fuel, accounting, managing, financing, fish processing, trading and marketing (Harper *et al.*, 2013; Thorpe *et al.*, 2014). These are labeled as supporting activities (Gereva & Vuki, 2010; Kleiber *et al.*, 2015; Tindall & Holvoet, 2008) or, when women are fishers (Béné *et al.*, 2009) in intertidal and shallow zones it is labeled as collection and gleaning and gathering (FAO, 2015a; Pálsson, 1989; Worldfish Center, 2010). Gender bias has implications for science, management, and the access to key resources. Most data measure only men's effort at sea from interviewing men (Kleiber *et al.*, 2015; Smith *et al.*, 2017), underestimating aggregate SSF economic contributions. Also, comprehensive ecosystem management – including of zones important for juvenile fish (e.g., seagrass beds, mangroves) – requires understanding all SSF practices (Kleiber *et al.*, 2015). Further, as women are often excluded from representing their concerns in the dominant fisheries governance processes (FAO, 2006; Okali & Holvoet, 2007; Porter, 2006), they are more vulnerable to tenure insecurity, marginalization and poverty (Harper *et al.*, 2013). Alternative SSF definitions are emerging. FAO's Voluntary Guidelines for Securing Sustainable Small-Scale Fisheries in the Context of Food Security and Poverty Eradication (SSF-Guidelines) defines SSFs with all activities along the relevant value chains – e.g., "pre-harvest, harvest and post-harvest" by men or by women (FAO, 2015a). Its implementation will shift SSF futures.

Challenges differ for inland fisheries facing agricultural runoff, introduced exotic species, and human uses (Youn *et al.*, 2014) such as hydropower, flood control, and irrigation (Baran *et al.*, 2007). In many developed countries, commercial fisheries have diminished in favor of alternative uses of freshwater, including recreational fishing, and scale again matters. Inland fisheries often feature small-scale harvesting (Bartley *et al.*, 2015) but large-scale, commercialized fisheries have large vessels and highly mechanized gear – e.g., the kilka fishery in the Caspian Sea (FAO, 1999), mechanized operations on lakes in Finland and the United States or estuaries in the Brazilian Amazon (Carolsfield, 2003; GLMRIS, 2012; Salmi & Sipponen, 2017) and long bag nets in the Tonle Sap Great Lake in Cambodia (Lamberts, 2001). Such operations may be more easily monitored and governed than dispersed fishers. Trade-offs between revenues and food security (Abila, 2003) arise for high-value exports (Lake Victoria Nile perch generated 250 million USD in 2012 (IOC, 2015)), given vulnerable stocks (Ermolin & Svolkinas, 2016).

2.1.18.4 Feedback loops and natural-social trajectories

Growing literature on social-ecological dynamics has largely explored actions (e.g. agriculture, fisheries, forestry, mining sectors) and the economic (e.g. trade, income, economic composition), and governance indirect drivers – alongside some work on positive and negative feedback loops, in a complex-systems sense of exacerbating or diminishing the forces going in a given direction.

Here we consider interactions and feedbacks that lead toward more or less desirable natural and social outcomes. This brings us full circle back to the trajectories highlighted in the Introduction.

The dynamics underlying development pathways described in the Introduction include feedback. Thus, as noted, initial conditions for the many consequential indirect drivers can lead to actions, aggregated impacts, changes in nature, shifts in NCP abundance or scarcity and, thus, changes in indirect drivers including values, prices, governance institutions, and more. Such feedback loops can push towards balancing or, instead, towards more extreme outcomes, both natural and social.

Below, we consider some relevant pieces of such feedback loops, although much remains to be studied concerning loops relevant for nature. First, we consider changes in trajectories, including abrupt changes, with feedback towards environmental degradation. Second, as part of responses to such trends, we consider individuals' and groups' feedback to governance responses. Finally, we scale upwards for possible feedback loops that lead in more desirable directions for nature.

2.1.18.4.1 Interactions, abrupt changes, and linked negative trends

Dramatic changes in nature can result from feedback that emerges from complex interactions between indirect and direct drivers – which can exacerbate the rates of degradation of nature. Regime shifts, for instance, are large, abrupt and persistent changes in the function and structure of systems (Scheffer & Carpenter, 2003). They occur at different spatial and temporal scales in marine and terrestrial systems (Rocha *et al.*, 2015). A 'regime shifts data base' documents over 30 different types of these abrupt changes (Figure S34) with >300 case studies based on a literature review of over 1000 scientific papers (Biggs *et al.*, 2015).

Regime shifts are increasingly observed. While they can occur naturally, under current trends of environmental forcing they might be more frequent and severe than observed. Climate change and food production have large forcing impacts (DeClerck *et al.*, 2016; Foley *et al.*, 2005;

Gordon *et al.*, 2008; Rocha *et al.*, 2015) and such shifts are expected to occur widely, but particularly in the Arctic (AMAP, 2012; Ford *et al.*, 2015; IPCC, 2013; Peterson & Rocha, 2016) where climate impact is felt relatively quickly. Another example of a regime shift is hypoxia in coastal systems, where oxygen levels fall low enough to produce 'dead zones' whose frequency and extent has risen across recent decades (Diaz & Rosenberg, 2008) and are more pronounced in the Northern Hemisphere, given common use of fertilizers. In the US only, more than 500 such 'lifeless' zones have been reported (Figure S35).

Shifts within the Arctic region have led communities to self-organize and to promote adaptive capacity (Huitric *et al.*, 2016), yet Arctic communities are, on their own, of course often limited in influencing the drivers of the regime shifts (Peterson & Rocha, 2016). Policies to manage many of the shifts that affect those communities require coordinated actions over scales which address the diversity of drivers (Rocha *et al.*, 2014).

Feedbacks between health and nature can arise when health and nature's status affect each other. The uses of antibiotics by humans (including over-use or mis-uses), for example, build resistance in nature (Laxminarayan *et al.*, 2013), thus contributing to negative impacts of nature on people. Chronic and infectious diseases and epidemic outbreaks shape household uses of nature, driving land management and dictating investments and policy. An E. coli outbreak changed landscape management in the US, for instance, as farmers eliminated hedgerows to avoid contamination by small mammal feces (Martin, 2006). In East Africa, poor health contributes to destructive and illegal fishing practices (Fiorella *et al.*, 2017), while sustainable agricultural practice is more common with improved access to anti-retroviral therapy (Damon *et al.*, 2015). Illnesses shift management of landscapes, e.g., malaria risk shapes tropical wetlands management (Malan *et al.*, 2009) while Zika control efforts include widespread insecticide use in the Americas and Pacific region (Blinder, 2016; Petersen *et al.*, 2016). Illness burdens – staggering globally and in sub-Saharan Africa and South Asia in particular – have implications for allocating budgets toward concerns deemed more immediate than nature. These kinds of interactions allow for unfortunate and linked trends in nature and human health.

2.1.18.4.2 Citizen feedback to governance

Well-informed citizens vote for representatives who share their views on the use of nature, in a democratic ideal. Yet, the fraction who vote has been well below 100%, globally. Voting may be irrational (Downs, 1957) and uninformed (Campbell *et al.*, 1960; Converse, 1964; Fiorina, 1981; Zaller, 1992), Studies find biases(Shogren & Taylor, 2008) and assess "nudges" around energy (Gillingham *et al.*, 2006; Sunstein & Reisch, 2014), including 'learning' via comparisons to neighbors (Allcott, 2011; Ayres *et al.*, 2013). In Ireland, real-time information affected behaviour (Gans *et al.*, 2013), although effects may decay without sustained information (Allcott & Rogers, 2014). 'Moral persuasion' (Ito *et al.*, 2018; Reiss & White, 2008) had effects only in the short-run, rising with income but lower for political conservatives (Costa & Kahn, 2013). Social identities matter (Bartels, 2002; Cassino & Lodge, 2007; Greene, 1999; Hillygus & Shields, 2014; Huddy, 2001; Kahneman & Tversky, 1979; Krosnick, 1991; Quattrone & Tversky, 1988). While values and identities may override (Kahan *et al.*, 2011; Layzer, 2006), so too do prior exposures and interactions (Brody *et al.*, 2008; Egan & Mullin, 2012). Framing around health (Myers *et al.*, 2012) and victims (Hart & Nisbet, 2012) can activate concerns and voting. Uncertain perceptions and a growing polarization and segmentation of media limits information (Hollander *et al.*, 2008).

Activists, firms, scientists and experts all inform both citizens and states (Keck & Sikkink, 1998), with influence via ideas and information, including from monitoring and connecting actors and setting agendas (Betsill & Corell, 2001; Wapner, 1995). Over time some NGOs have acquired roles in environmental regimes – nationally and internationally (Wapner, 1995). Some focus on facts: 'epistemic communities' (Sebenius, 1992) influence choice given uncertainties about social and physical processes (Adler & Haas, 1992) by developing knowledge or solutions, plus lobbying (Gough & Shackley, 2002). International learning can facilitate improved policies (Adler & Haas, 1992).

Free flow of information, civil liberties and regime receptiveness to citizen demands all suggest better environmental quality for democracies (Payne, 1995). Yet India – the largest democracy – faces severe environmental quality issues while Singapore ranks high alongside Norway and Sweden (EPI, 2018). Citizens can be aware of issues regardless of state-provided information, as they live with the problems (Arvin & Lew, 2011; O'Rourke, 2004; Winslow, 2005). Further, less democratic regimes do not restrict all information (King *et al.*, 2013 on censorship within China), even if any information that could galvanize collective action might be restricted. Participation modes for environmental actors have included protests in Vietnam and Myanmar to demand less degradation (Doyle & Simpson, 2006; O'Rourke, 2004). While that is not always effective, not all environmental participation is effective in democracies. Pavlinek & Pickles (2004) note the prioritization of the economy instead of environment in post-Soviet Central and Eastern Europe (CEE), yet Midlarsky (1998) sees "no uniform relationship between democracy and the environment" while Pellegrini and Gerlagh (2006) and Pellegrini (2011) suggest effects of democracy in decreasing degradation are overstated and that corruption could undermine all.

Leaders' incentives have mattered (Congleton, 1992; Ward *et al.*, 2014), e.g., private income gains from polluting and extracting (Deacon, 1999; McGuire & Olson, 1996; Olson, 1993). If the elites lose rents in stringent regulatory regimes, while the benefits of conservation are diffuse, leaders may not strengthen nature (Bernauer & Koubi, 2009; Cao & Ward, 2015). The time horizons matter too. Lasting institutions include legislatures (Gandhi, 2008; Gandhi & Przeworski, 2007; Svolik, 2012) and political parties (Brownlee, 2007), which can extend the temporal perspective.

In the 1970s, state policies were often varied command and control limits on pollution through output or technology requirements (Coglianese & Lazer, 2003). While relatively easy to implement, these have inefficiencies due to inflexibility (Jaffe *et al.*, 1995) and the distrust and adversarial legalism that often results. As Kagan (1991) describes, legal rules and adversarial procedures for resolving disputes often lead to costly winner-takes-all judicial battles with both cost and delays. This can result from a closed-door approach in which agencies ignore firm and local knowledge, lowering 'buy-in' (Beierle & Konisky, 2001; Coglianese & Lazer, 2003). This can create opportunities for 'capture' by interest groups (Oates & Portney, 2003) that have influence in traditional regulatory processes – often reflecting the power of concentrated production and finance. Recently, greater attention has been given to collaborative governance by public and private actors (Fiorino, 2006): "agencies directly engage non-state stakeholders in a collective decision-making process that is formal, consensus-oriented, and deliberative" (Ansell & Gash, 2008). Walker et al (2015) describe such approaches: first, the state informs and educates citizens via public meetings and notifications; second, regulating entities request public input on policies, as through comments, though technical complexity requires the agency to do more policy formulation; and third, more complete collaboration where agencies and private stakeholders equally construct new policies.

Water management provides some examples, from across the globe, of significant variation in such processes. In Singapore, a Public Utilities Board (PUB) manages electricity, gas and water supply plus legislation to address sewerage, effluents, drinking water quality and more (Luan, 2010). After focusing on construction and maintenance, it now also does 'demand management' to encourage citizens to conserve. India's National Water Policy is coordinated by the Ministry of Water Resources as a tool for planning and development of water resources. Adopted in 1987, this legislative pact was relaunched in 2012 to emphasize water as an 'economic good' and, thus, promotes efficient use and conservation. Beyond potable water access, a recent addition is flow in water channels to meet ecological needs. Canada also adopted a Federal Water Policy in 1987, noting intensive consultation with diverse stakeholder groups given two key objectives: improve the quality of the water resource; and advocate freshwater use in an efficient and equitable way, coherent with the social, economic and environmental needs of present and future generations.

2.1.18.4.3 Scaling up and extending positive responses

Multiple existing initiatives have both a positive potential and some potential to be scaled up for moderating negative impacts on nature and good quality of life, toward more sustainable futures. One compilation is the "Seeds of Good Anthropocenes" initiative[3] that aims to explore and articulate positive futures (Bennett *et al.*, 2016). Up to 500 initiatives which demonstrate elements of positive futures have been identified **(Figure 2.1.22)**, towards testing theories about how desirable transformative pathways can supported (Pereira *et al.*, 2018). They include social movements, ways of living or doing things, technologies and designs, and governance. For example, Yachay City of Knowledge is a "New City" under development in rural Ecuador, conceptualized to be a technological research and innovation hub containing research facilities, a working university, and bio-tech companies. "Tribal parks" are an example of Aboriginal people being recognized as co-managers of national parks in Canada[4]. The Foundation for Ecological Security is an Indian NGO which is working to reduce poverty by helping communities organize to restore their ecosystems while also enhancing their livelihoods in over 8,000 village institutions in 31 districts across 8 states, having already supported some form of restoration of over 1 million ha while training 350,000 people in both ecological restoration and management of village institutions[5].

Quite broadly, many voices have called for alternatives to current global development pathways (see also chapters 5 and 6). There are calls for 'degrowth', with changes in social and political priorities (Odum & Odum, 2006). Ecological sustainability and social justice are called out, e.g., "an equitable downscaling of production and consumption that increases human well-being and enhances ecological conditions at the local and global level" (Schneider *et al.*, 2010). Whether this will be widely embraced or scaled up as a goal remains to be seen.

Consumer-driven initiatives to demand sustainable land-use management and the restoration of degraded lands have arisen in recent decades (IPBES, 2018a). Companies have responded by committing to reduce impacts upon nature and the rights of local communities, including taking steps to, e.g., eliminate deforestation due to supply chains by

2020. State and civil-society groups have committed to restore hundreds of millions of hectares of degraded lands. Following all this, the finance sector is starting to make explicit commitments to reduce its environmental impacts.

Other alternatives to global development pathways have emphasized how nature's contributions are valued and currently marketed – versus how they could or should be. These have highlighted incentives and the potential from clear ownership and use rights, with private-market interactions that facilitate price feedbacks to address scarcities. For example, when an earthquake shuts down copper mines, the futures market quickly lowers expectations of supply, through higher prices, that in turn shifted any number of private plans, from computer wiring through kitchen redesign. Most generally, following signals of natural scarcities, relevant decisions have adjusted to help.

Industrial ecologists note that responses to environmental quality and natural resource scarcities have been considerably more complex, even if guided by a simple pursuit of profits. Paraphrasing Frosch & Gallopoulos (1989), the wastes from one industry can be the inputs for others, reducing the total usage of all raw materials as well as the generation of pollution into the environment. This has occurred in residences, too, with 'gray water' from apartments feeding urban roof gardens. While all of that requires coordination, in principle it is motivated by private costs or profits alone.

Limits on such useful feedback processes have included: information; rights; and transaction costs. Since the private payoffs from resource use and environmental degradation drive private choices, in many settings even commendable private responses have come up far short of social sensibility. The simple, obvious and pervasive reason for this is that private actors often have not taken into account how other people would lose (or gain) from those actors' choices concerning degradation. Sometimes actors did not know about effects on others, which suggests potential from initiatives such as efforts to communicate with relevant actors, e.g., via certifications of production processes. Yet often people simply have not in their daily decisions given equal attention to effects on others – even though, clearly, there exists both altruism and various private provisions of public goods. Thus, even if fully informed about effects on others, private actors were not bound to incur costs to benefit others, and often did not, raising questions about public roles concerning those affected.

When people affected by others' behaviours had the publicly defended right to clean air, or water, producers degrading others' environment and resources were forced to get consent and, at times, compensate the affected. That shifts private costs and benefits and, thus, plans. Given appropriate public frameworks, those signals of the need to adjust were stronger as scarcities in nature rose, shifting further the trade-offs for degrading production. Yet such frameworks often were lacking.

When rights were clear, and incentives aligned, actors gained in their own management decisions from information due to assessments – even by others. It appears as though larger fisheries, which tend to be more systematically assessed, are doing better in maintaining fish stocks, on average, than small, formally unassessed fisheries (Costello *et al.*, 2012). Even so, there can exist multiple stable points of equilibria within such fully informed social-ecological systems, given social and natural sources of feedback. Fishing effort responds often to the state of the fish stock, which is in turn affected by fishing-effort levels. If sustainability-oriented decision rules imply that the fishing effort falls as the scarcity of the fish rises, then they can stabilize stocks as can regulations informed by ecological and human response models (Yun *et al.*, 2017) **(Figure 2.1.23)**.

Notwithstanding the many types of past contributions to support nature, by many private actors, many outcomes in private contexts often have indicated a need for public responses to scarcities. Public actors with overarching mandates have not only set up appropriate frameworks to address trade-offs – leading to quantity and price policies – but also lowered solutions' transaction costs. For instance, states have required information, e.g., labeling with energy use for refrigeration or, more involved, certifications of legal sourcing for forest products, under which public rejections of illegally harvested timber

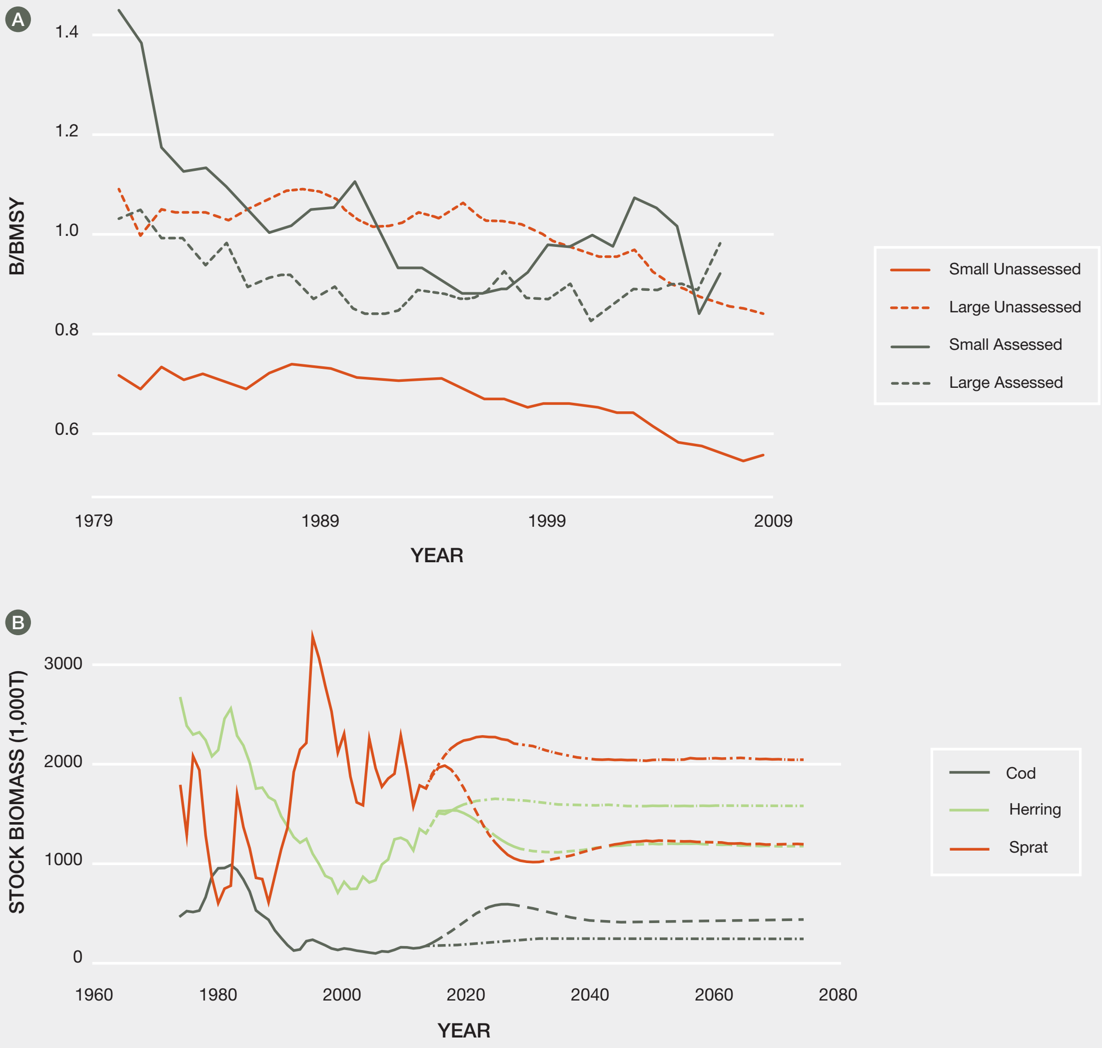

Figure 2 1 23 **Fisheries can show positive trends into the future when adequately managed and governed.**

Ⓐ The ratio of observed biomass to the biomass that would provide maximum sustainable yield (B/Bmsy) has stabilized for small and large fisheries that are being constantly monitored (assessed). Ⓑ Fisheries can stabilize at different equilibria level when managed for single-species (dashed lines), and under ecosystem-based management (dot-dash lines).
Sources: Costello et al. (2012), Yun *et al.* (2017).

have occurred (e.g., under the EU's FLEGT or the U.S. Lacey Act).

Further, many crucial incentives and empowerments of private actors involved the creation or the enforcement of some form of right, such as indigenous lands or smallholder land tenure or firms' concessions for timber harvesting or the right to clean air as implied by limitations on emissions. Like private choices, establishment of such limitations or rights has tended to respond to scarcity.

Stepping back, while in the past a large set of such institutions have generated social efficiency, as well as equity when attention has been given to that critical outcome as well, in practice there exist considerable institutional challenges. Just as private collective action to form institutions was not always successful – given multiple determinants of such coordination – public processes will not always effectively address environmental and resource scarcity. Some actors do not wish to do so. This suggests considerable attention is needed to environmental politics, alongside policy design.

CHAPTER **2.2**

STATUS AND TRENDS – NATURE

EXECUTIVE SUMMARY

1 **Humanity is now a dominant influence on nature worldwide *(well established*) {2.2.5, 2.2.7}, with many impacts having accelerated rapidly in the 20th century *(well established)* {2.2.5.2}.** Humanity has influenced nature significantly since prehistory, both positively (e.g., development of agrobiodiversity) and negatively (e.g., extinction of megafauna and flightless island birds) *(well established)* {2.2.4, 2.2.5.1}; but nature – including species, their genes and populations, communities of interacting populations, ecological and evolutionary processes, and the landscapes and ecosystems in which they live – is now declining rapidly and many facets of nature have already been much reduced *(well established)* {2.2.5}, supporting suggestions that Earth has entered the Anthropocene.

2 **Much of nature has already been lost, and what remains is continuing to decline {2.2.5.2}**. Indicators of the extent and structural condition of ecosystems, of the composition of ecological communities, and of species populations overwhelmingly show net declines over recent decades; most of the exceptions are themselves symptoms of damage (e.g., the biomass of prey fish has increased, but this is because humanity has harvested most of the bigger fish that prey on them; and terrestrial vegetation biomass – though still only around half its natural baseline level – has increased slightly in recent decades, mainly because elevated CO_2 slightly increases photosynthesis) *(well established)* {2.2.5.2.1, 2.2.5.2.3, 2.2.5.2.4}. Some declines have slowed (e.g., the extent of forests is reducing less quickly than in the 1990s) and some have even been reversed (e.g., area of tree cover is increasing), but others are accelerating (e.g., most of the total extinction risk to species is estimated to have arisen in the past 40 years (*established but incomplete*).

3 **The degree of transformation of ecosystems from natural to human-dominated varies widely across terrestrial, inland water and marine systems, and geographically within many systems {2.2.5.2.1, 2.2.7}. Over 30% of the world's land is now agricultural or urban, with ecosystem processes deliberately redirected from natural to anthropogenic pathways. Human drivers extend so widely beyond these areas that as little as 13% of the ocean and 23% of the land is still classified as "wilderness" – and these areas tend to be remote and/or unproductive (e.g., tundra, oceanic gyres) *(well established)* {2.2.5.2.1}.** The most accessible and hospitable biomes either have been almost totally modified by humans in most regions (e.g., Mediterranean forests and scrub, temperate forests) or show maximum levels of conversion to anthropogenic biomes or "anthromes" (e.g., conversion of most temperate grassland to cultivated land and urban areas) *(well established)* {2.2.7.7}. Although the five freshwater and marine biomes cannot be settled and physically transformed in the same way as terrestrial biomes, they too range from unaltered to highly degraded *(well established)* {2.2.5.2.1, 2.2.7}. No global data exist on the extent of aquaculture and intensively-used coastlines, but sensitive coastal and nearshore ecosystems – such as coral reefs, mangroves and saltmarshes – are already well below natural baseline levels and continuing to decline rapidly *(established but incomplete)* {2.2.5.2.1}. Such habitats provide important resources and protection for hundreds of millions of people.

4 **Globally, the net rate of loss of forests that are not managed for timber or agricultural extraction has halved since the 1990s (*established but incomplete)*, but declines continue in the tropics *(well established)*; and intact forest landscapes – large areas of forest or natural mosaic with no human-caused alteration or fragmentation detectable by satellites – are still being lost from both high and low income countries *(established but incomplete)* {2.2.5.2.2}.** Forests in temperate and high latitudes have been expanding through afforestation programmes or vegetation succession after land abandonment, but the often highly biodiverse tropical forests continue to dwindle (*well established*) {2.2.5.2.1, 2.2.7.2}. The rate of loss of intact tropical forest landscapes has increased threefold in 10 years due to industrial logging, agricultural expansion, fire and mining (*well established*) {2.2.5.2.1}. Primary boreal and temperate forests are also increasingly degraded worldwide *(well established)* {2.2.7.3}.

5 **Hotspots of rare and endemic species have on average suffered more degradation of ecosystem structure and biotic integrity than other areas, despite their importance for global biodiversity *(well established)* {2.2.5.2, 2.2.7.15}.** Across a range of taxonomic groups, 7.3% of the land is particularly rich in

species that are not found elsewhere. Indicators of ecosystem structure, community composition and species populations are ~ 20% lower in these 'hotspots' of rare and endemic species and are declining much faster (median = 74% faster), than across the world as a whole *(established but incomplete)* {2.2.5.2}. In the oceans, approximately half the live coral cover on coral reefs – among the most species-rich habitats on earth – has been lost since the 1870s, with accelerating losses in recent decades due to climate change exacerbating other drivers; the live coral cover on coral reefs has declined by 4% per decade since 1990 *(established but incomplete)* {2.2.5.2.1}.

6 **Human actions threaten more species with global extinction now than ever before *(well established)* {2.2.5.2.4}: extrapolating from detailed 'bottom-up' assessments of species in the best-studied taxonomic groups suggests that around one million animal and plant species already face extinction, and that a third of the total species extinction risk to date has arisen in the last 25 years *(established but incomplete)* {2.2.5.2.4}.** Land/sea-use change is the most common direct driver threatening assessed species, followed by (in descending order of prevalence) direct exploitation, pollution, invasive alien species and climate change *(well established)* {2.2.6}. The rate of species extinction is already at least tens to hundreds of times higher than it has averaged over the past 10 million years, and it is set to rise sharply still further unless drivers are reduced *(well established)* {2.2.5.2.4}. Available population trend records show widespread and rapid declines in species' distributions and population sizes *(established but incomplete)* {2.2.5.2.4}; these declines can both reduce the contributions species make to people and perturb local ecosystems with often unpredictable results**.** The prevalence of extinction risk in high-diversity insect groups is a key unknown, and knowledge of population trends is still very incomplete, especially for non-vertebrate species.

7 **A 'top-down' analysis of the number of species for which sufficient habitat remains suggests that as many as half a million terrestrial species of animal and plant may already be doomed to extinction because of habitat loss and deterioration that have already taken place *(established but incomplete)* {2.2.5.2.4}.** These 'dead species walking' come about because responses to drivers can take many years to play out *(well established)* {2.2.5.2.4}. Habitat restoration could save many of these species if done soon after the original loss or degradation of habitat. The estimate of half a million terrestrial species, including over 3,000 vertebrate and 40,000 plant species, is produced by unprecedented integration of global environmental data with distributional information for over 400,000 terrestrial species of invertebrate, vertebrate and plant; although it is broadly consistent with the 'bottom-up' estimate of a million threatened species across the terrestrial, freshwater and marine realms, it uses entirely separate data and analysis.

8 **Transformation of ecosystems to increasingly intensive human use has enabled a small fraction of species to greatly expand their distribution and increase in abundance.** Nearly one fifth of the Earth's surface is at risk of plant and animal invasions, impacting native species, ecosystem functions and nature's contributions to people, as well as economies and human health. Over 6000 plant species are known to be invasive somewhere in the world. The number of invasive alien species and the rate of introduction of new invasive alien species seems higher than ever before and with no signs of slowing *(established but incomplete)* {2.2.5.2.3}.

9 **Human actions are driving widespread changes in organismal traits *(well established)* {2.2.5.2.5} and reductions in genetic diversity *(established but incomplete)* {2.2.5.2.6}. Many species are evolving rapidly as they adapt to human drivers of change, including some changes – such as resistance to antibiotics and pesticides – that pose serious risks for society *(well established)* {2.2.5.2.5, Box 2.5}, which evolutionary-aware policy decisions and strategies can mitigate *(established but incomplete).*** Populations have lost about 1% of their genetic diversity per decade since the mid-19th century; wild populations whose habitats have been fragmented by land-use change have less genetic diversity than those elsewhere; and mammalian and amphibian genetic diversity is lower where human influence is greater *(established but incomplete)* {2.2.5.2.6}. Although the spread of agriculture led to the development of many races and varieties of farmed animals and plants, the modernization of agriculture has seen many of these go extinct: by 2016, 559 of the 6,190 domesticated breeds of mammals used for food and agriculture (over 9 per cent) had become extinct and at least 1,000 more are threatened *(established but incomplete)* {2.2.5.2.6}. Case studies have demonstrated rapid trait changes in response to all main direct drivers and some clear examples of rapid evolution – e.g., trophy-hunted bighorn sheep have evolved smaller horns – and many species show rapid evolution in cities *(well established)* {2.2.5.2.5, **Box 2.5**}. Evolutionary-aware strategies can help to prevent undesirable evolution (e.g., of resistance to control measures in pests and diseases) and to promote desirable evolutionary outcomes (e.g., reduced reproduction of mosquitoes that transmit malaria) *(established but incomplete)* **{Box 2.5}**.

10 **The global loss of forests, rates of species extinction, and average losses of originally-present biodiversity from terrestrial ecological communities all transgress proposed precautionary 'Planetary Boundaries' *(established but incomplete)* {2.2.5.2.1,**

2.2.5.2.3}. Transgressing these boundaries may risk tipping the Earth system out of the environmentally stable state it has been in throughout the history of civilization, though debate about both the reality and position of the boundaries continues *(inconclusive)* {2.2.5.2.1, 2.2.5.2.3}***.*** The loss of forests and tree cover (reduced to 68% and 54%, respectively, of their historical baselines) exceed the proposed Planetary Boundary for land-system change (i.e., no more than a 25% reduction in forests) *(established but incomplete)* {2.2.5.2.1}, below which the biosphere's contribution to global climate regulation may become critically compromised *(unresolved)* {2.2.5.2.1}. The global rate of species extinction is already at least tens to hundreds of times higher than the average rate over the past 10 million years and is accelerating *(established but incomplete)* {2.2.5.2.4}, exceeding the proposed boundary and potentially impoverishing the biosphere's capacity to adapt to possibly abrupt environmental change *(unresolved)* {2.2.5.2.4}. On average, terrestrial ecological communities worldwide have lost at least 20% of their originally-present biodiversity *(established but incomplete)* {2.2.5.2.3}, double the proposed safe limit beyond which the short-term healthy functioning of biomes may become compromised *(inconclusive)* {2.2.5.2.3}.

11 **Land-use change has had the largest relative negative impact on nature for terrestrial and freshwater ecosystems, mainly through habitat loss and degradation; whereas in marine ecosystems, direct exploitation of organisms (mainly fishing) has had the largest relative impact, followed by land/sea-use change *(well established)* {2.2.6.2}. The multiple components of climate and atmospheric change (e.g., changing temperature, rainfall and atmospheric CO_2 levels as well as ocean acidification) are already significant drivers of change in many aspects of nature but are not usually the most important drivers at present (*well established*) {2.2.6.2}.** The relative impact attributable to each driver also varies markedly among components of nature, taxonomic groups, regions and biomes (*established but incomplete*) {2.2.6.2, 2.2.7}. For instance, species abundance is mostly affected by land-use change in the terrestrial and freshwater systems but by direct exploitation in the marine realm. Invasive alien species often have a strong impact on oceanic island assemblages worldwide (*well established*) {2.2.3.4.1, 2.2.5.2.3}, and invasive pathogens are implicated in the rapid declines of many amphibian species (*well established*) {2.2.5.2.3}. Coral reef bleaching is a direct consequence of ocean temperature increase *(well established)* {2.2.7.15}. Temperature increase is the main factor at high latitudes both on land and in the oceans {2.2.5.2.5, 2.2.7.3, 2.2.7.5, 2.2.7.12, 2.2.7.15}. The drivers of change are all interconnected; as such they are compromising the Earth's living systems as a whole to a degree unprecedented in human history.

12 **The world's major ecosystems vary in both the intensity of drivers they face and their ability to withstand them, with some close to potential collapse.** The bleaching of shallow coral reefs during hotter and more frequent marine heat waves, coupled with intensifying fishing and intensification of coastline use, indicate a type of ecosystem whose thresholds of resilience are being exceeded *(well established*) {2.2.7.15}. In the Mediterranean forests, woodlands and scrub of many regions, wildfires are starting earlier in the year and increasing in number, coverage and severity which, coupled with their increasing human population due to attractiveness for settlement and the associated expansion of urban and cultivated areas, may indicate a transformation at the biome scale *(established but incomplete)* {2.2.7.4}.

13 **Many practices of Indigenous Peoples and Local Communities (IPLCs) conserve and sustainably manage, wild and domesticated biodiversity *(well established)* {2.2.4}. A high proportion of the world's terrestrial biodiversity lives in areas managed and/or held by Indigenous Peoples *(well established)* {2.2.4}, where ecosystems and ecological communities tend to be more intact and declining less rapidly than elsewhere *(established but incomplete)* {2.2.5.3.1}.** Practices that contribute to biodiversity include co-production of highly diverse cultural landscapes that are very heterogeneous ecologically and often rich in both wild and domesticated species {2.2.4.1, 2.2.4.2, 2.2.4.3}; contributing to agrobiodiversity by selection, domestication and maintenance of wild races and varieties of plants and animals {2.2.4.4}; traditional management practices that enhance natural resilience (e.g., by targeted burning) {2.2.4.5}; increasing landscape-scale net primary biomass production (e.g., by adaptive grazing and burning regimes) {2.2.4.6}; and protecting areas from external exploiters, e.g., slowing the spread of intensive monocrop agriculture in recognized indigenous territories {2.2.4.7}. However, unsustainable practices are becoming increasingly common in some regions traditionally managed by Indigenous Peoples and Local Communities as lifestyles, values and external pressures change with globalization *(well established)* {2.2.4}. At least a quarter of the global land area is traditionally owned, managed[1], used or occupied by Indigenous Peoples. These areas include approximately 35 per cent of the area that is formally protected, and approximately 35 per cent of all remaining terrestrial areas with very low human intervention (*established but incomplete*) {2.2.5.3.1}; all these figures would rise if other local communities were considered*.* For the global indicators that could be compared between these indigenous lands

1. These data sources define land management here as the process of determining the use, development and care of land resources in a manner that fulfils material and non-material cultural needs, including livelihood activities such as hunting, fishing, gathering, resource harvesting, pastoralism and small-scale agriculture and horticulture.

and the world as a whole, nature has declined by 30% less, and has declined 30% more slowly in recent years, in the indigenous lands *(established but incomplete)* {2.2.5.3.1}.

14 **Indigenous Peoples and Local Communities report that the nature important to them is mostly declining: among the local indicators developed and used by Indigenous Peoples and Local Communities, 72 per cent show negative trends in nature that underpin local livelihoods and well-being *(well established)* {2.2.5.3.2}, which they mainly attribute to land-use change and climate change; the relative importance of these drivers varies among regions and major ecosystem types *(established but incomplete)* {2.2.6.3}.** Natural resource availability is generally decreasing; time needed or distance travelled to harvest resources is increasing; culturally salient species often have negative population trends; native newcomer species arrive as climate changes (e.g., southern species to arctic areas); new pests and invasive alien species colonize; natural habitats are lost, especially forests and grazing lands, while remnant ecosystems degrade and their productivity decreases; and the health condition and body size of wild animals decrease *(established but incomplete)* {2.2.5.3.2}. The drivers to which IPLCs most often attribute the mostly negative trends in nature (in decreasing order of prevalence and based on >300 indicators) were land-use change (e.g., tropical forest monocrop conversions, expansion of settlements and discontinued traditional land management practices); climatic changes, such as droughts and the increasingly unpredictable annual distribution of rainfall; arrival of new pests and invasive alien species; changing range of wild species; floods (as a combined effect of climate and land-use changes); and finally overexploitation of resources by outsiders and locals (e.g., logging and overgrazing) *(established but incomplete)* {2.2.6.3}.

15 **Whereas scientific observations on the status of nature have for centuries been valued, systematically recorded, retained and synthesized in scientific outputs, indigenous and local knowledge of nature has been largely disregarded, is still being lost, and has rarely been synthesized (*well established)* {2.2.2.2}.** The synthesis of trends in nature observed by Indigenous Peoples and Local Communities has been hindered by the lack of regional and global institutions that would gather, aggregate and synthesize local data into regional and global summaries *(well established)* {2.2.2.2, **Box 2.6**}, but such efforts are emerging. Many of the aspects of nature monitored by Indigenous Peoples and Local Communities are reasonably compatible with indicators used by natural scientists but tend to be more local in scale and more directly connected to elements of nature that underpin nature's contributions to people (*well established)* **{Box 2.6}**, highlighting the importance of recording and synthesizing them. The spread of modern lifestyles and technologies into many indigenous and other local communities may threaten the current diversity of conceptualizations of nature and of ways of learning about and from it, as well as resource management practices that could ensure sustainable human-nature relations (*well established*) {2.2.2; 2.2.4}.

16 **This global assessment has been able to make use of much more, better, more comprehensive and more representative information than was available even a decade ago *(well established)* {2.2.1}. Though uncertainties and gaps in knowledge remain, there can be no doubt that nature is continuing to decline globally *(well established)* {2.2.5, 2.2.7} in response to direct human-caused drivers *(well-established)* {2.2.6}.** Some of the most important knowledge gaps are: global syntheses of indigenous and local knowledge about the status and trends in nature; quantitative syntheses of the status and trends of parasites, insects, microorganisms, and biodiversity in soil, benthic and freshwater environments, and of the implications for ecosystem functions; quantitative syntheses of human effects on ecosystem processes involving interactions among species, e.g., pollination; quantitative global overviews of many vital ecosystem functions; syntheses of how human impacts affect organismal traits and genetic composition; and a more comprehensive understanding of how human-caused changes to one Essential Biodiversity Variable class (e.g., ecosystem structure) ramify through to the others (e.g., community composition) and to nature's contributions to people.

2.2.1 INTRODUCTION

The definition of 'nature' used in this assessment encompasses all the living components of the natural world. Within the context of western science, it includes biodiversity, ecosystems (both structure and functioning), evolution, the biosphere, humankind's shared evolutionary heritage, and biocultural diversity (Díaz *et al.*, 2015). Within the context of other knowledge systems, such as those of Indigenous Peoples and Local Communities (IPLCs), nature includes categories such as Mother Earth and systems of life, and it is often viewed as inextricably linked to humans, rather than as a separate entity (Díaz *et al.*, 2015). IPBES' mandate includes bringing together evidence from diverse knowledge systems, including indigenous and local knowledge, and respecting diverse worldviews. Section 2.2.2 explores the diversity of worldviews and of ways in which nature is conceptualized and outlines how they are changing.

Nature shows enormous geographic variation, at both large and small spatial scales. Associated with the range of spatial scales, there are also a broad array of institutions and governance of nature, varying from local communities through to international **(Figure 2.2.1)**, which all mediate both how nature contributes to people (NCP) and how people affect the state of nature (Brondizio *et al.*, 2009; Duraiappah *et al.*, 2014; see chapters 2.1 and 2.3). At the broadest geographic scale, nature can be described according to different units of analysis (defined in chapter 1) – from coniferous and temperate forests to tropical and subtropical savannas to coastal areas and deep oceans. However, within each of these units, there is variation among regions, landscapes and habitats (both terrestrial and marine) and at all levels of diversity. Section 2.2.3 tackles this complexity, organising nature's many dimensions into six classes – ecosystem structure, ecosystem function, community composition, species populations, organismal traits and genetic composition (Pereira *et al.*, 2013) – and outlines how the global patterns of each today still largely reflects the action of natural evolutionary and ecological processes through earth's history (Bowen *et al.*, 2013; Pinheiro *et al.*, 2017; Rex & Etter, 2010; Ricklefs, 2004; Whittaker *et al.*, 2001; Willig *et al.*, 2003). Illustrative examples mostly highlight aspects of nature that underpin some of its most critical material, non-material and regulating contributions to people.

Humanity has been reshaping patterns in nature for many millennia (Lyons *et al.*, 2016). Many IPLCs view themselves as partners in a reciprocal process of nurturing and co-production, rather than as extrinsic drivers of change (see chapter 1). Section 2.2.4 describes the land- and sea-management practices and processes through which IPLCs have co-produced and maintained nature and continue to do so over much of the world. At least a quarter of the global land area is traditionally owned, managed[2], used or occupied by Indigenous Peoples (at least double if local communities are considered). These areas include approximately 35 per cent of the area that is formally protected, and approximately 35 per cent of all remaining terrestrial areas with very low human intervention (Garnett *et al.*, 2018).

Whether viewed as an extrinsic driver or an intrinsic part of nature, humanity's actions now increasingly overprint the global patterns that natural processes have produced, at all scales **(Figure 2.2.1)**. Section 2.2.5 considers human-caused trends in nature alongside current status. Because many anthropogenic drivers of change have intensified greatly since the mid-20th century (chapter 2.1, Steffen *et al.*, 2015a), the discussion of trends focuses on changes since 1970, but also briefly describes earlier positive and negative effects. As well as many science-based indicators, this section includes the first global synthesis of local trend indicators observed by IPLCs. Section 2.2.6 synthesizes which of the main direct drivers – land/sea-use change, direct exploitation, climate change, pollution and invasive alien species (see chapter 2.1) have had the greatest relative impact on nature in recent decades as judged by analysis of global indicators and the perceptions of IPLCs of the drivers behind the local changes they observe.

This subchapter's mostly global focus is balanced by brief accounts of the status, trends and drivers of change in nature within each unit of analysis (Section 2.2.7), and by also highlighting three other categories of landscape that add to global nature and nature's contributions to people disproportionately to their geographic extent: insular systems, areas particularly rich in endemic species, and hotspots of agrobiodiversity (Section 2.2.3.4). The contribution of agrobiodiversity to people is obvious; but nature contributes to people in a myriad of ways, from local-scale flows of material and non-material benefits to households and communities, to global-scale regulation of the climate **(Figure 2.2.1)**; chapter 2.3 synthesizes these contributions and how the trends in nature are changing them.

Synthesizing and mapping variations in the state of nature across the globe and over time has been greatly facilitated by major recent advances in remote observation of biodiversity and ecosystems, in modelling and in informatics. For example, remote-sensing technologies can now provide data on ecosystem structure and function – and increasingly on abundance and distribution of biodiversity – across wide areas, with high spatial and temporal resolution (Pettorelli *et*

2. These data sources define land management here as the process of determining the use, development and care of land resources in a manner that fulfils material and non-material cultural needs, including livelihood activities such as hunting, fishing, gathering, resource harvesting, pastoralism and small-scale agriculture and horticulture.

al., 2016), though deriving estimates of global biodiversity change from remotely-sensed data is not yet straightforward (Rocchini *et al.*, 2015). Recording of indigenous and local knowledge (Lundquist *et al.*, 2016) can also add relevant information over smaller scales. In addition, advances in species delimitation, identification and discovery have been facilitated by new DNA technologies (e.g., Kress *et al.*, 2015) and this in conjunction with data aggregators and repositories, such as GBIF (www.gbif.org), OBIS (www.iobis.org) and Genbank (Benson *et al.*, 2013), make hundreds of millions of species occurrence records and gene sequences freely available. Ever-improving metadata mean that such data – despite still providing very uneven coverage taxonomically, geographically, temporally and ecologically (Akçakaya *et al.*, 2016; Hortal *et al.*, 2015) – can increasingly be put to a wide range of uses. This expanded biodiversity informatics landscape is increasingly well connected (Bingham *et al.*, 2017), facilitating the synthesis of raw observations by new analytical interfaces (e.g., Jetz *et al.*, 2012; Ratnasingham & Hebert, 2007; see www.iobis.org).

A growth in multi-institution collaboration has also resulted in the expansion of networks collecting parallel data, often in many countries (e.g., Anderson-Teixeira *et al.*, 2015; Kattge *et al.*, 2011), while the establishment of the Biodiversity Indicators Partnership and GEO BON has helped to coordinate biodiversity observations, modelling and indicators (Mace & Baillie, 2007; Pereira *et al.*, 2013; Scholes *et al.*, 2008). The development and widespread adoption of meta-analyses and systematic reviews – facilitated by bibliographic databases, online publishing and the growth of open data – has helped researchers to synthesize previously disparate evidence (e.g., Gibson *et al.*, 2011; Root *et al.*, 2003). Synthesis of indigenous and local knowledge on status and trends of nature unfortunately still lags much behind scientific synthesis, though much progress is underway in documenting local observations of trends and aggregating these to global scale (see e.g., Forest Peoples Programme *et al.*, 2016a), and co-producing knowledge from ILK and science.

These developments in observation, aggregation, collaboration, modelling and synthesis mean that this global assessment has been able to draw on much better and more integrated information than was possible even only a decade ago.

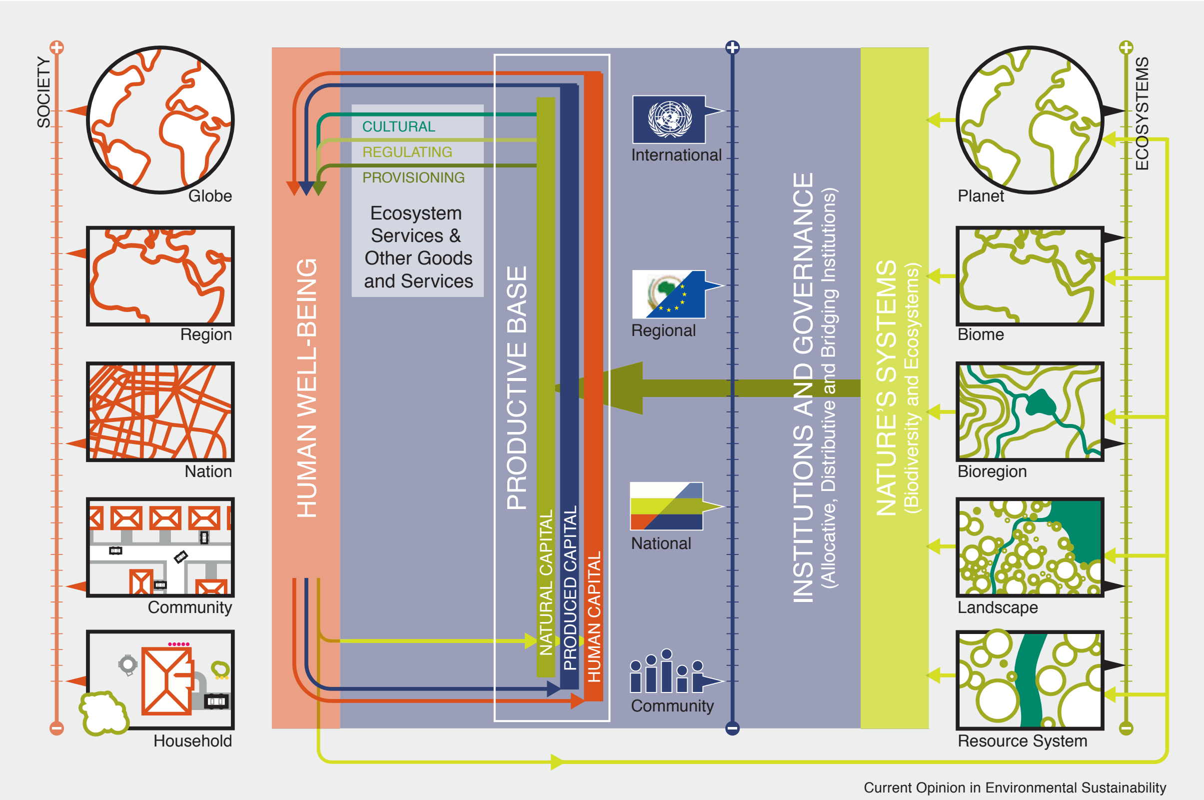

Figure 2 2 1 **The hierarchical scales of nature, society and governance.**

This figure has many parallels with the IPBES conceptual framework (see chapter 1), but emphasises how the multiple scales of governance influence both nature's contributions to people (arrows passing through the box labelled 'Ecosystem services & other goods and services) and societal feedbacks onto nature's systems. Figure from Duraiappah *et al.* (2014).

2.2.2 DIVERSE CONCEPTUALIZATIONS OF NATURE AND PLURALISTIC KNOWLEDGE SYSTEMS

Nature is conceptualized differently by people having different relationships with it, including farmers, herders, fishers, hunter-gatherers, other Indigenous Peoples and Local Communities, urban communities, practitioners (such as hydro- and forest engineers), natural scientists, social scientists and artists. Different conceptualizations of nature lead to different types of experiential learnings and knowledge systems. Within historical times some knowledge systems such as "scientific knowledge", have gained a universal acknowledgement, while other knowledge systems such as "indigenous knowledge" have been less well appreciated and valued, especially in terms of the information they provide on nature both locally and at larger scales.

2.2.2.1 Indigenous Peoples' and Local Communities' conceptualizations and knowledges of nature (IPLCs)

There are many different ways that societies consider nature. There are those which consider humans as an element of nature. In contrast, others consider humans as starkly different from nature beyond the obvious biological commonalities with, and dependence on, the rest of the living world. Here we use the term 'conceptualizations of nature' to refer to views and perspectives on nature by different societies, which establish meanings to the links between humans and elements of nature, and form principles or ontologies that guide interactions with nature (Atran *et al.*, 2002; Ellen & Fukui, 1996; Foucault, 1966). Anthropological studies comparing many societies across the world have classified the large diversity of situations met into general models, based on the degree of continuity or separation between nature and people. Most societies that recognize a continuity between humans and nature conceptualize elements of nature as agents with an interiority, intentions or an attractivity (e.g., plants) that facilitates interactions between humans and non-human (Descola, 2013; Ellen, 2006). Models showing strong linkages between humans and non-humans are for instance animism and totemism (Descola, 2013; Harvey, 2006; Sahlins, 2014). Analogism, a widespread conception of nature widely studied and typical of some Asian societies and in Europe differentiates humans and non-humans although they share some properties from microcosms (cells) to macrocosms (planets) and are made of similar elements (wind, water, fire etc.). Within such conceptualizations humans are able to find in nature many signs that guide a large set of practices, including health, food, agriculture (e.g., Friedberg, 2007; Zimmermann, 1988). Naturalism – the principle that theoretically characterizes modern western societies and western science – emerged with philosophers such as Descartes and emergence of modernity – conceives natural as an external element, starkly different from humans, an object of experimentation using analytical approaches for better productivity or control (Foucault, 1966).

Such principles continue to influence people's attitudes to environmental and sustainability issues today. While science is therefore supposed to be neutral, Ellen (1996), shows that scientific disciplines have their own ways of conceiving the environment that serve the interest of particular groups, whether they belong to the conservation movement, have linkages to industries, churches, political parties, academics, Indigenous People, or governments. Thus, even science and modernity establish intricate links between nature and culture and the naturalist approach is rarely void of cultural worldviews.

The IPBES conceptual framework puts a strong emphasis on reflecting that different societies, and different individuals within societies, have different views on desirable relationships with nature, the material versus the spiritual domain, and the present versus the past or future (Díaz *et al.*, 2015, 2018; see also chapter 1, Section 1.3.1).

Indigenous and local knowledge systems are the knowledge of Indigenous Peoples and Local Communities who mostly live within natural and rural environments and make a living through – and define their cultural identity upon – an intimate relationship with nature, land and sea (Douglas *et al.*, 1999; Garnett *et al.*, 2018; Sanga & Ortalli, 2003; Warren & Slikkerveer, 1995). Indigenous knowledge systems differ from science in many ways, viewing nature holistically i.e., as said above linking all elements of nature to people in ways that enables continuities either through considering the inner self of non-humans (animism and totemism) or through common properties (analogism), all of which are linked to the social and decision-making spheres (Descola & Palsson, 1996; Ellen, 2002; Motte-Florac *et al.*, 2012; Tengö *et al.*, 2017; see more in chapter 1). Building upon similar overall principles linking humans to nature, local knowledge systems are locally rooted, tested and culturally transmitted (Molnar & Berkes, 2018). Many of these local knowledge systems vary depending on sociocultural and religious background and also the degree of integration in modern lifestyles, a situation also encountered among indigenous groups. For example, European small-scale multi-generational farmers, herders and fishers, and some foresters and hydro-engineers using and managing the same natural resource for generations may have strong connections to their local nature and a deep understanding of local ecological processes and may feel themselves as part of nature (Babai & Molnár, 2014; Kis *et al.*, 2017; Whiteman & Cooper, 2000).

2.2.2.2 Collaboration between knowledge systems, changing conceptualizations

Conceptualizations of nature and related knowledge and practices are not static. They may change considerably over time at different temporal scales. Knowledge co-production between knowledge systems, interdisciplinary cooperation and modern lifestyles may accelerate change, and may foster or threaten conceptualizations and knowledge that ensure sustainable human-nature relations and consequently status and trends in nature.

Conceptualizations of nature may change in relation to levels of collaboration between knowledge systems and/ or between scientific disciplines. Although disciplinary approaches in natural or social sciences (e.g., between functional and evolutionary ecology, sociology and

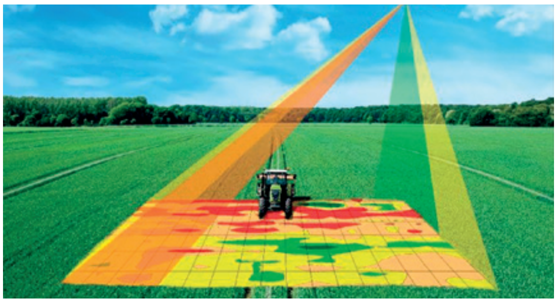
Box 2 1 Conceptualizations of nature – examples.

Conceptualizations of nature – whether indigenous, scientific, laic, practitioner or something else – have a fundamental impact on our behaviour, relations to nature and thus on our impact on nature. Examples in this box aim to present some contrasting conceptualizations of nature.

In Indigenous conceptualizations of nature people often argue: 'All is One', 'All is connected'. April White, a Haida Indigenous artist from British Columbia created a series of prints to help negotiations of Haida fishery management with the government. These prints feature a herring-consuming predator (e.g., a whale) inside of a herring, a way reflecting the nurturing role the fish plays for so many organisms at all levels of the ecosystem. She argues that art possesses a unique storytelling power that science can stand from benefit from, "Art has a voice where a scientist might not." (Vogl, 2017).

The romantic idyllic view of nature emphasizes purity of nature, laws of nature, and harmony. This view had a huge impact on the notion of 'balance of nature' (cf. also Carson's Silent Spring), and the development of some wilderness-oriented protected area management philosophies (source: Károly Telepy, Rocky landscape, 1870, @KOGART).

Perspectives matter. Those who experienced this view of our Earth often argue for a shift in their perspective: "You also notice how the atmosphere looks and how fragile it looks," astronaut Scott Kelly said. "It makes you more of an environmentalist after spending so much time looking down at our planet." (https://mashable.com/2016/03/04/scott-kelly-year-space-environmentalist/?europe=true). (Earthrise from the moon during Apollo 8, NASA).



Precision agriculture is becoming one of the dominant views about arable areas in our modern era. It aims to provide enough food for humanity with a very high level of anthropogenic assets, dominating natural processes with advanced technology. This conceptualization also changes considerably our relations to the nature we manage (source: https://www.innovationtoronto.com/2016/09/precision-agriculture/).

economics) are often still dominant, the trends towards collaborative, inter- and transdisciplinary and participatory research with stakeholders on nature and human-nature relations are now opening new options for learning. This may help develop new concepts of interactions between nature and humans that foster social-ecological systems and resilience thinking (Berkes *et al.*, 2000), relational thinking (Chan *et al.*, 2016), deep ecology (Naess, 1973), the revisiting of the religious linkage to nature through portraying the ideas of Saint Francis of Assisi (Francis, 2015) or the pluralistic IPBES concept of nature's contributions to people (Díaz *et al.*, 2018). Within conservation biology, views on the relationship between people and nature have continued to change over recent decades: nature for itself, nature despite people, nature for people, and people and nature (Mace, 2014). Some conservation biologists integrate indigenous and local knowledge to help develop new concepts and practical actions for better conservation (Ghimire *et al.*, 2008; Molnár *et al.*, 2016). In ethnobiology, a discipline dedicated to study human-nature relations, there is a shift from more academic research objectives to more practical approaches including working together with Indigenous Peoples and Local Communities to co-develop sustainable management practices (Barrios *et al.*, 2012; Berkes, 2004; Hamilton & Hamilton, 2006; Newing *et al.*, 2011).

Global processes include different contrasting tendencies such as commodification of nature, urbanization, spread of modern lifestyles, green movements, respect for the rights of Mother Nature (such as allocating personhood status to rivers), and wider acknowledgment of local space-based knowledge systems linked to complexity of social-ecological systems. These tendencies are likely to change human-nature relations and our conceptualizations of nature. In addition, hybridization of scientific and indigenous and local knowledge of nature is accelerating all over the world and changing our values regarding nature.

Although indigenous and local knowledge (ILK) is locally-based, it is increasingly being shared between holder groups through local to global networks (e.g., Forest Peoples Programme *et al.*, 2016a; ICCA Consortium: www.iccaconsortium.org), and by social media.

People living in urban settings also have diverse and changing conceptualizations of nature depending on their ethnic and family history, education, religion, and their everyday experiences with urban and non-urban nature and modern technology (Coyle, 2005; Loughland *et al.*, 2003).

Scientific observations on the state of nature from a scientific perspective have for centuries been valued, systematically recorded, retained in the accumulating scientific literature and synthesized. In contrast, much indigenous and local knowledge has not been recorded in a systematic fashion and thus much knowledge has been lost (see more in chapter 3 and 6). This means that records and synthesis lag far behind natural science, so there are very few resources on the status and trends of nature as observed by Indigenous Peoples and Local Communities with global coverage (Forest Peoples Programme *et al.*, 2016a; Posey, 1999). Because of this imbalance, although most of the evidence in this chapter came from the context of natural sciences, a special effort has been made to also accommodate indigenous and local knowledge on nature.

2.2.3 OVERVIEW OF NATURE

2.2.3.1 Essential Biodiversity Variables

Given the complexity of unit and scale when considering nature, a global system of harmonized observations has been proposed for the study, reporting, and management of biodiversity change (Pereira *et al.*, 2013). These have been termed 'Essential Biodiversity Variables' (EBV) (see https://portal.geobon.org) **(Figure 2.2.2)**. Below we describe what is known about the current global distribution of nature using this framework, giving examples of the current knowledge on those aspects of the variables that are particularly important in terms of NCP. We then go onto discuss the contribution of Indigenous People and Local Communities to the co-production and maintenance of nature, particularly genetic, species and ecosystem diversity. This is followed by a discussion on the status and trends in nature based on these EBVs with particular emphasis on the past 50 years – trends that have resulted in the current state of nature.

2.2.3.2 Ecosystem structure

At the global scale, the terrestrial realm can be demarcated according a pattern of ecosystem structure (Units of Analysis) **(Figure 2.2.2A)** where different dominant species cause the ecosystems to differ in structural complexity (e.g., tropical rainforest vs tundra or deserts) and the natural resources they can provide to people. Sometimes referred to as 'biomes' (Olson *et al.*, 2001) and (for anthropogenic units) 'anthromes' (Ellis & Ramankutty, 2008), the current observed units of structural complexity across the globe occur as result of processes that span millions of years and primarily reflect a combination of water-energy dynamics, geology and tectonic activity (Willis & McElwain, 2014). Demarcation of marine biomes according to ecosystem structure is an ongoing task – new habitats are still being discovered (Costello *et al.*, 2010; Snelgrove, 2016) – but here too, long-term environmental and geological processes determine structure: e.g., warm-water shallow coral reefs can grow only within a narrow environmental envelope (Kennedy *et al.*, 2013).

An understanding of global ecosystem structure is particularly important in determination of variations in photosynthetic biomass. These variations in biomass in turn have many effects on multiple aspects of NCP, from the type and quantity of material and non-material benefits available to local people, to global regulation of climates through carbon sequestration and the water cycle (Pan *et al.*, 2011, 2013). Total photosynthetic biomass in the ocean is less than 1% of that on land (totals of 3 PgC for marine versus 450–650 PgC on land), and this amount is mostly regulated by nutrient availability, light availability and temperature (IPCC, 2013).

2.2.3.3 Ecosystem function

This term is used to describe functions provided by the stocks of materials in an ecosystem (e.g., carbon, water, minerals, and nutrients) and the flows of energy through them. The functioning of an ecosystem is therefore reliant upon a complex array of abiotic and biotic factors and underpinned by many of the variables of nature described below. When considering global ecosystem functions that are important to people, two of the most fundamental are net primary production (NPP) and carbon sequestration.

Net primary production (NPP) represents the uptake of CO_2 by plants during photosynthesis minus the amount of CO_2 that is lost during respiration. Its importance is that it provides the main source of food for non-photosynthetic organisms in any ecosystem – including humans. NPP therefore underpins many critical aspects of nature's contribution to people (Imhoff *et al.*, 2004). Worldwide, humanity now appropriates 24% of terrestrial NPP, with over 50% being appropriated across many of the intensively farmed regions (Haberl *et al.*, 2007). NPP shows very large spatial variation **(Figure 2.2.2B)**. Terrestrial NPP varies from < 100 gC/m2/year (in polar and desert regions) to 1500 gC/m2/year in the humid tropics (Zak *et al.*, 2008) (see also **Table 2.2.2**), in response to levels of sunlight, temperature, water availability, CO2, nutrient availability and the type of vegetation (Nemani *et al.*, 2003). In the oceans, NPP is largely determined by nutrient availability (e.g., Howarth, 1988; Huston & Wolverton, 2009), varying from undetectably low in nutrient-poor gyres to 500 gC/m2/year in the coastal shelves and upwelling regions.

Carbon sequestration is another critically important global ecosystem function provided by nature. This represents the difference between CO_2 uptake by photosynthesis and release by respiration, decomposition, river export and anthropogenic processes such as harvesting and biomass burning. At present about 60% of the atmospheric CO_2 emitted into the atmosphere by fossil fuel emission each year (9.4 PgC / year in 2008–2017) is sequestered by nature's carbon sink in land (3.2 PgC /year in 2008–2017) and in the oceans (2.4 PgC / year in 2008–2017) (Le Quéré *et al.*, 2018), providing a vital role in regulating the Earth's climate.

Spatial and temporal patterns in carbon sinks and sources are very heterogeneous. Forest ecosystems (e.g., tropical and boreal forests) on average are carbon sinks due to CO_2 fertilization, climate change, and recovery from historical

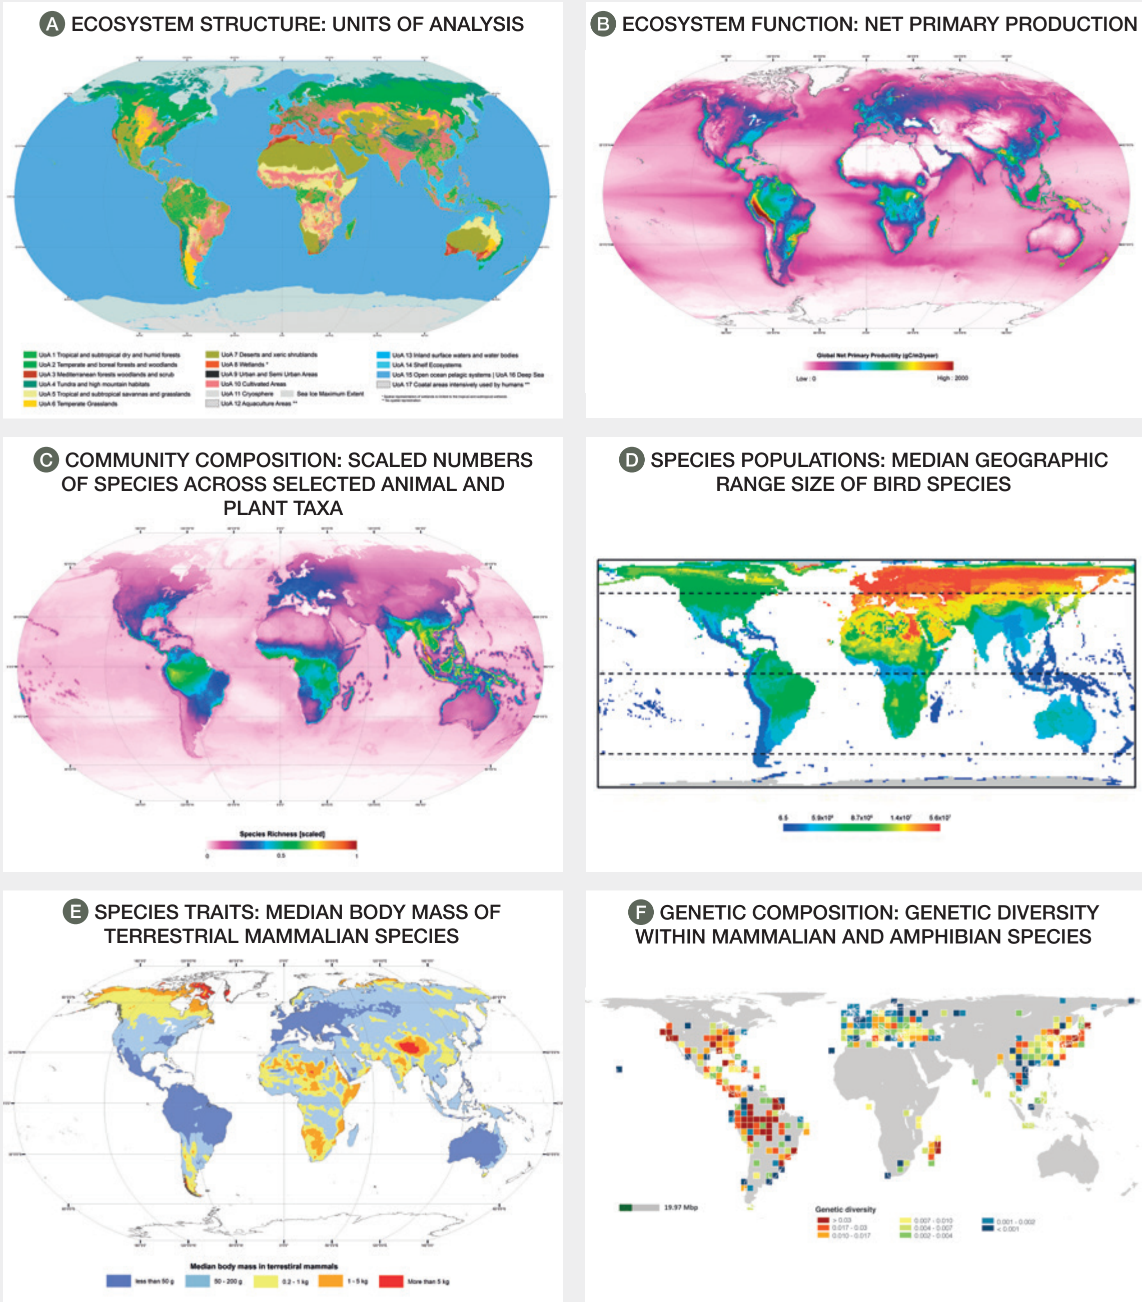


Figure 2 2 2 **Maps of the current distribution of key aspects of nature as measured using the key metrics described in the Essential Biodiversity Variables framework.**

A: **Ecosystem structure** – Extent of natural and anthropogenic units of analysis considered in this assessment. B: **Ecosystem function** – Net primary production (Behrenfeld & Falkowski, 1997; Zhao & Running, 2010). C: **Community composition** – Relative numbers of species per 0.5-degree grid cell, averaged across terrestrial amphibians, reptiles, mammals (data from the IUCN Red List of Threatened Species, https://www.iucnredlist.org/resources/spatial-data-download) and vascular plants (Kreft & Jetz, 2007), freshwater species (data from Collen *et al.*, 2014) and marine species (data from Selig *et al.*, 2014). D: **Species populations** – Median geographic range size of bird species (Orme et al., 2006). E: **Species traits** – median body mass of mammalian species (Santini *et al.*, 2017). F: **Genetic composition** – Average genetic diversity within mammalian and amphibian species within each grid cell (Miraldo *et al.*, 2016).

land-use changes (Kondo *et al.*, 2018; Pan *et al.*, 2011). Between 2000 and 2007, the global forest carbon sink is estimated to have removed 2.4 billion tons of carbon per year from the atmosphere (Pan *et al.*, 2011). Much of this was stored in tropical forests (0.8 billion tons per year), followed by temperate forests (0.8 billion tons per year) and boreal forests (0.5 billion tons per year). Soils are also an important component of terrestrial carbon sinks. For example, 50–70% of the carbon in boreal forests is stored in the soils, particularly in roots and root-associated fungi (Clemmensen *et al.*, 2013). Furthermore, some regions, such as tropical forests and peatlands (e.g., Baccini *et al.*, 2017) are vulnerable to becoming large CO_2 emitters when there is a change in their structure and resulting function (e.g., due to land-use change).

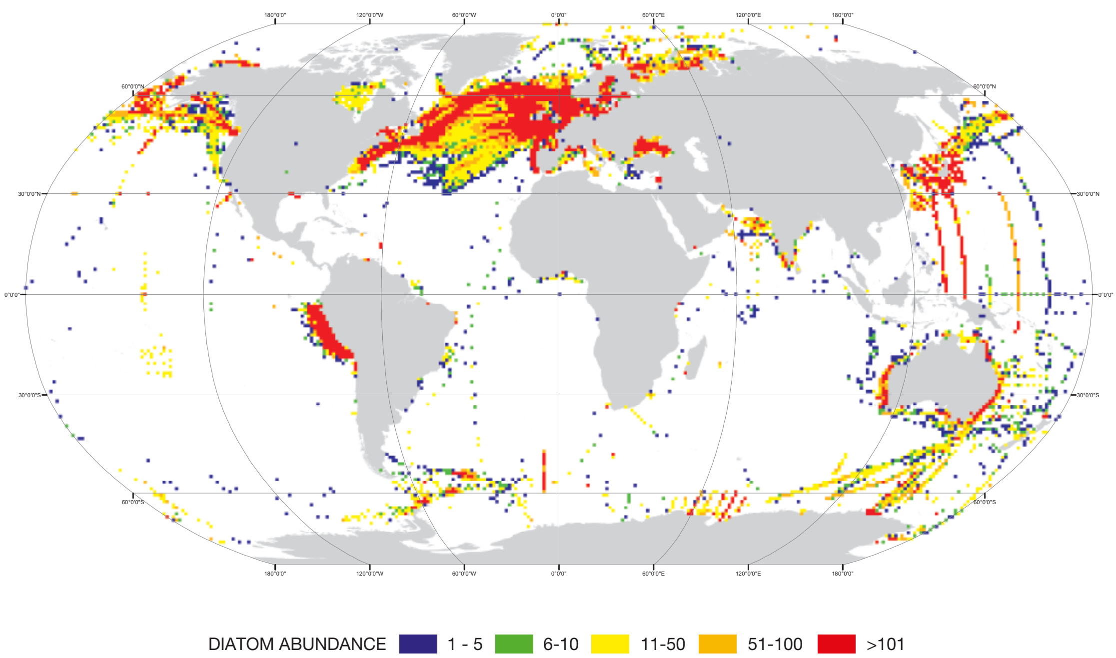
In the ocean, CO_2 is exchanged with the atmosphere primarily by air-sea exchange based on inorganic carbon chemistry. Ocean general circulation, and marine biological processes also affects CO_2 exchange with atmosphere. The CO_2 in the ocean is exported effectively to the deep ocean via the biological pump. Therefore, ocean NPP is one of the most essential factors to determine ocean CO_2 sequestration.

2.2.3.4 Community composition

The term ecological community is used to describe an assemblage of plants, animals and other organisms that are interacting in a unique habitat where their structure, composition and distribution are determined by environmental factors such as soil type, altitude and temperature and water availability. At a global scale there is high variation in the distribution and diversity of different communities, with changes occurring across latitudinal and altitudinal gradients in both terrestrial and ocean environments. Probably one of the most well-known global trends in community composition is the latitudinal gradient in diversity on land, with the highest number of species per unit area at the equator and the lowest at the Poles (e.g., mammals, birds, reptiles, amphibians, and vascular plants; see Willig *et al.*, 2003 for a review). Species interactions also appear to be stronger in the tropics (Schemske *et al.*, 2009). However, some groups show departures from this trend, for example bees and aphids (Kindlmann *et al.*, 2007).

Box 2 2 **Global patterns in composition of marine diatoms (algae).**

Marine plankton communities, including diatoms contribute around 20% of global primary productivity and are hugely significant in biogeochemical cycles and functioning of aquatic food webs (Armbrust, 2009). Until recently little had been known about variations in the diversity and abundance of these communities across the global oceans. A recent global study of diatoms (Malviya *et al.*, 2016) demonstrated that although most species were found at all sites, 10 genera accounted for more than 92% of the samples indicating the dominance of a few types in the world's oceans. Overall the highest abundance of diatoms was found in regions of high productivity (upwelling zones) and the high latitude Southern Oceans.



Global abundance of diatom (Bacillariophyta) species obtained from OBIS datasets (April 2018) each square is coloured according to the abundance of diatoms species observed in the area of 100 sqkm) (from Malviya *et al.,* 2016).

In marine environments, many groups also show a trend of decreasing species richness from the equator to the poles (e.g., fish, tunicates, crustaceans, mollusks, brachiopods, corals, foraminiferans; and see Tittensor *et al.*, 2010), but specific groups or habitats can substantially deviate from this trend (see Willig & Presley, 2018 for a review). For example, baleen whales have their highest diversity at southern subpolar and temperate latitudes (Kaschner *et al.*, 2011). Biodiversity at the seafloor has a maximum at or close to continental margins in areas of high carbon flux (Menot *et al.*, 2010; Woolley *et al.*, 2016).

In addition to these global patterns of diversity and abundance in community composition, there are also a number of well-defined communities of plants and animals associated with geographical isolation (insular systems), endemism (biodiversity hotspots), and diversity of species of plants, crops and microorganisms useful to people (agrobiodiversity hotspots). These areas are home to a disproportionately high proportion of the world's species, including for example the Eastern Arc mountains of Africa (Burgess *et al.*, 2007) and Pacific seamounts (Richer de Forges *et al.*, 2000); the narrow distributions of most of these species makes them intrinsically more susceptible to drivers of change. Many of these areas typically constitute only a small fraction of a biome or IPBES terrestrial and aquatic unit of analysis, raising the risk that their status, trends and projected futures may not be clearly reflected in assessments of nature at those large scales.

A description of each will be briefly discussed in turn.

2.2.3.4.1 Insular systems

An insular environment or "island" is any area of habitat suitable for a specific ecosystem that is surrounded by an expanse of unsuitable habitat. Examples of insular systems include mountain tops, lakes, seamounts, enclosed seas, and isolated islands or reefs. These systems have several important properties that set them apart from non-insular systems and thus dictate their specific consideration in this assessment.

Biotas in insular environments are often depauperate relative to biotas in similar but well-connected environments – because relatively few individuals of relatively few species arrive from across the surrounding unsuitable habitat (Brown & Kodric-Brown, 1977; Vuilleumier, 1970). This limited colonization results in many "empty niches" into which the few colonizing species can diversify, leading to a high proportion of endemic species (e.g., Australia, Keast, 1968; Galapagos, Johnson & Raven, 1973; Madagascar, Wilmé *et al.*, 2006; mountain tops Steinbauer *et al.*, 2016). The result can be a collection of unique species with little or no taxonomic equivalent on the mainland, such as flightless cormorants and marine iguanas in Galapagos or honeycreepers and silverswords in Hawai'i. The limited colonization of islands can also lead to "enemy release," where the few colonists lose their defenses against former competitors, parasites, or predators, including humans. The resulting "evolutionary naïveté" renders many taxa in insular systems especially susceptible to exploitation by humans and to the spread of invasive species, especially predators and diseases (Sih *et al.*, 2010). Examples of the resulting biological catastrophes include the wholesale extinction of birds after the arrival of humans in New Zealand (Bunce *et al.*, 2005, 2009), the arrival of avian malaria in Hawaii (Warner, 1968), and the arrival of brown tree snakes in Guam (Savidge, 1987).

Many of these problems facing insular taxa are compounded when the insular habitats are very small and isolated, including tiny remote Pacific islands, alpine lakes, and dessert oases. In addition to exacerbation of these general problems of insularity, especially small insular systems often have a narrow range of environmental conditions to which local organisms are precisely adapted, along with very limited genetic variability. As a result, changing environmental conditions (e.g., climate warming or invasive alien species) that eliminate suitable habitat can be hard to mitigate through movement or adaptive responses (e.g., Corlett & Westcott, 2013; Courchamp *et al.*, 2014; Vergés *et al.*, 2014). Particularly obvious in this respect is the shrinking habitat of cool-climate organisms existing on mountain-top sky islands surround by unsuitable warm conditions. Finally, the small population sizes typical of species living in small insular habitats can lead to genetic drift and inbreeding that greatly reduce genetic variation in some situations. As insular taxa are often very local, rare, unique, and vulnerable, active and specific conservation efforts are critical. On the one hand, it is particularly important to limit biological invasions, as the effects for insular taxa are often severe and irreversible. On the other hand, insular taxa can often benefit from efforts to increase population sizes through habitat preservation and restoration, and to increase connectivity among isolated populations of a given species.

2.2.3.4.2 Hotspots of endemism and rarity

"Biodiversity hotspot" was a term originally proposed to describe communities of terrestrial plants and animals that contained a high concentration of endemic species yet had lost more than 70% of their original cover due to land-use change (Mittermeier *et al.*, 2011, 2004). There are now 35 terrestrial hotspots that cover only 17.3% of the Earth's terrestrial surface, characterized by both exceptional biodiversity and considerable habitat loss (Marchese, 2015).

In the oceans, the concept of hotspots of endemism is less clear since a high potential for species dispersal and only a few efficient large-scale barriers hamper the development and maintenance of endemism hotspots. However, there are important exceptions from this rule and some hotspots in species richness and endemism exist. For example, the warm-water shallow coral reefs provide the habitat for estimated 8 x 10^5-2 x 10^6 species (Costello *et al.*, 2015; Knowlton *et al.*, 2010) especially in the Indo-Pacific region. They are, together with Indo-Pacific seamounts, vents and seeps, deep cold coral reefs, shelves around New Caledonia, New Zealand, Australia and the Southern Ocean (Kaiser *et al.*, 2011; Ramirez-Llodra *et al.*, 2010), not only hotspots in species richness and functional biodiversity but also in endemism due to spatial isolation from other habitats or differences in environmental conditions. Marine range rarity is most obvious in Indo-Pacific coastal regions and off Mesoamerica (Roberts *et al.*, 2002; Selig *et al.*, 2014). Also, the deep sea is rich in species and habitats (Knowlton *et al.*, 2010), home to a conservatively estimated 5 x 10^5 macrofaunal species (Snelgrove & Smith, 2002).

Marine phylogenetic uniqueness is most obvious in vent and seep communities since not only single species but also larger older groups of related species (such as families) only occur in such habitats (Van Dover *et al.*, 2018). Some of the unique macroorganisms such as the *Riftia*-tubeworms and vesicomyid clams depend on a symbiosis with chemosynthetic bacteria as well as archaea. Most of these marine systems need special attention because they are increasingly impacted by the exploitation of natural and mineral resources by human activities. In addition, such ecosystems are especially vulnerable due to the rarity of species in the sense of small distribution ranges and their narrow tolerance windows as a result of a strong adaptation to their environment conditions.

Determining the distribution of most vulnerable species (i.e., those rare species with a small range distribution and/or ecological tolerance) is also an issue for terrestrial plants and animals. In the hotspots approach described above, which based on total richness of endemics, there tends to be an overrepresentation of wide-ranging species and some of the rarest and most threatened species that are range-restricted are not highlighted. It can therefore be a poor indicator of the most effective areas for targeted species conservation (Jetz & Rahbek, 2002; Margules & Pressey, 2000; Orme *et al.*, 2005). An alternative approach is to use a measure such as range-size rarity (also called "endemism

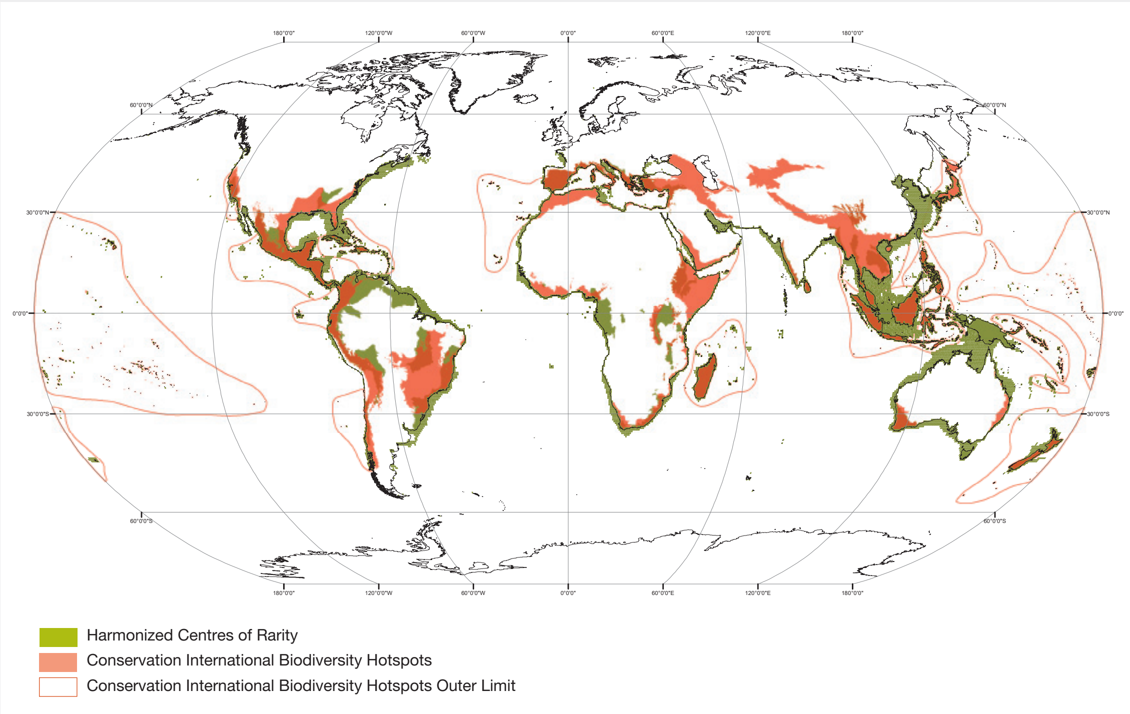


Figure 2 2 3 **Harmonized centres of rarity, representing 7.3% of the land surface and 5% of the marine surface (https://mol.org/patterns/raritycenters; see Supplementary Materials).**

Also indicated are the spatial extent of Conservation International's Biodiversity Hotspots demonstrating large regions where the two measures do not overlap.

richness", or "weighted endemism"; Crisp *et al.*, 2001; Kier & Barthlott, 2001; Williams *et al.*, 1996). In this approach range-size rarity is given as the count of species present in a region, weighted by their respective range proportion inside the region (Moilanen, 2007; Pollock *et al.*, 2017; Veach *et al.*, 2017). Using this approach to determine a set of global centres of endemism richness for vascular plants, terrestrial vertebrates, freshwater fishes and select marine taxa, indicates that harmonized centres of rarity cover 7.3% of the land surface and 5% of the marine surface (**Figure 2.2.3**; for a full description of methodology and details of taxa analysed see Supplementary Materials). Some of the indicators of nature reported below are sufficiently spatially resolved to allow their global status and trends to be compared to the status and trends within these.

2.2.3.4.3 Hotspots of agrobiodiversity

Agrobiodiversity is the defined as "the variety and variability of animals, plants and micro-organisms that are used directly or indirectly for food and agriculture, including crops, livestock, forestry and fisheries. It comprises the diversity of genetic resources (varieties, breeds) and species used for food, fodder, fibre, fuel and pharmaceuticals. It also includes the diversity of non-harvested species that support production (soil micro-organisms, predators, pollinators), and those in the wider environment that support agro-ecosystems (agricultural, pastoral, forest and aquatic) as well as the diversity of the agro-ecosystems" (CBD, 2000). Agrobiodiversity is therefore a vital component of healthy diverse diets and of sustainable systems that provide multiple benefits to people (Biodiversity International, 2017).

Globally a very large number of crop and domestic animal species, landraces, breeds and varieties, together with their wild relatives, contribute to food security (Dulloo *et al.*, 2014; Gepts *et al.*, 2013; Jacobsen *et al.*, 2015). Yet most human food comes from a relatively small number of plants and animals. Of the Earth's estimated 400,000 plant species, two thirds of which are thought to be edible, humans only eat approximately 200 species globally (Warren, 2015), and just four crops (wheat, rice, maize and potato) account for more than 60% of global food energy intake by humans (FAO, 2015b). The primary regions of diversity of major agricultural crops are mostly tropical or subtropical (**Figure 2.2.5**; Khoury *et al.*, 2016), though many of these crops are grown well beyond their areas of origin and maximum diversity; on average, over two thirds of nations' food supplies come from such 'foreign' crops (Khoury *et al.*, 2016). The location and conservation of hotspots of diversity of landraces, breeds and varieties therefore play a critical role in proving a gene pool and

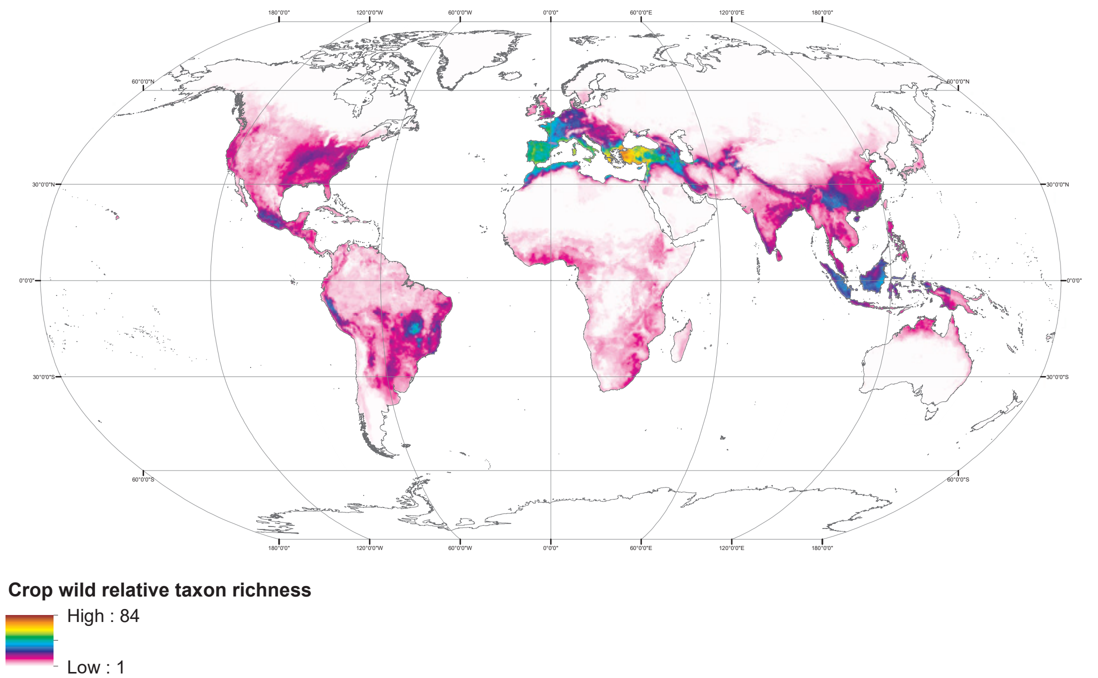

Figure 2 2 4 **Number of crop wild relative species currently known and their global distribution (redrawn from Castañeda-Álvarez *et al.*, 2016).**

variety of traits that may provide resilience against climate change, pests and pathogens (Jacobsen *et al.*, 2015). One branch of agrobiodiversity that has long been recognized in this respect are crop wild relatives (CWR) (Vavilov, 1926). CWRs are the ancestral species or other close evolutionary relatives from which present-day crops evolved, and they are essential to maintaining a pool of genetic variation underpinning our current crops. Their conservation is particularly important given that current crops have heavily depleted gene pools resulting from complex domestication processes, human selection and diffusions of crops and domestic animals, and ongoing diversification (Ellis, 2018; Harlan & de Wet, 1971; Larson & Fuller, 2014; Stépanoff & Vigne, 2018; Vigne *et al.*, 2012; Willcox, 2013; Zohary *et al.*, 2012).

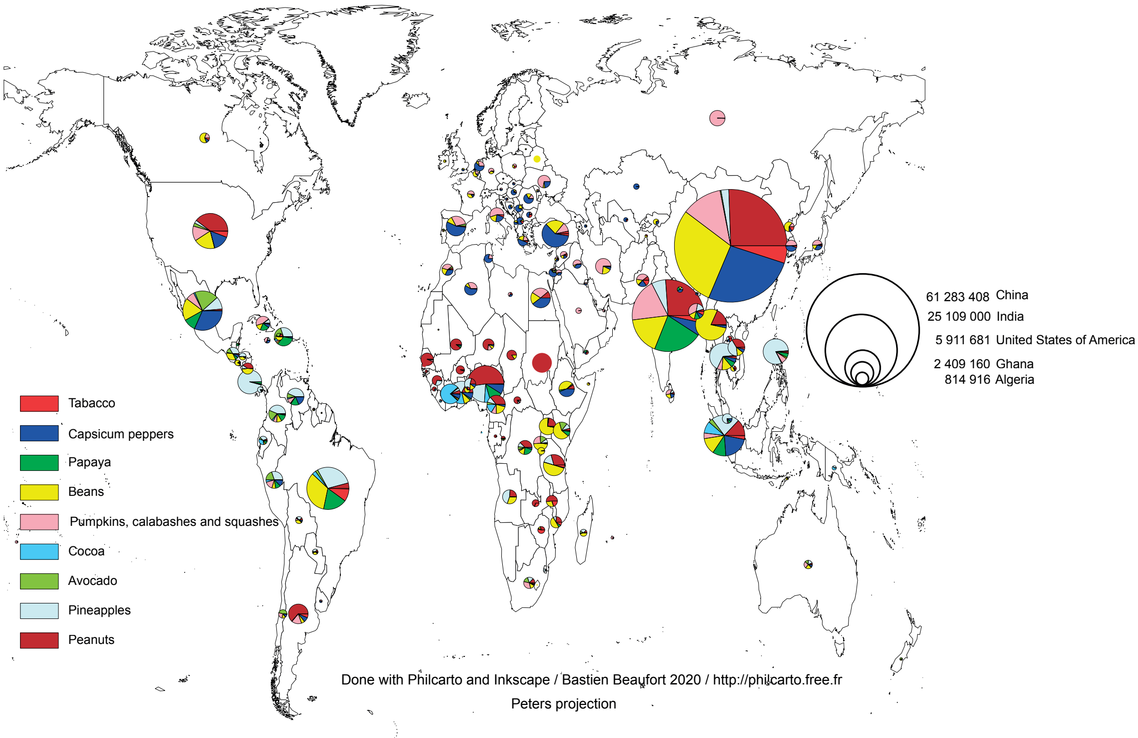
Vavilov (1926) originally recognized eight centres of crop domestication containing high numbers of CWRs. More recent mapping work (e.g., Castañeda-Álvarez *et al.*, 2016; Vincent *et al.*, 2013) suggests that there are many more regions where CWR occur and although the current richness hotspots align with traditionally recognized centres of crop diversity, other regions such as central and western Europe, the eastern USA, South-Eastern Africa and northern Australia also contain high concentrations of richness of CWRs **(Figure 2.2.4)**.

However, not all crop domestication and diversification has taken place near the areas of CWR's origins (Harlan & de Wet, 1971). New genomic tools and morphometric analyses are suggesting that many crops may have multi local areas of origin (e.g., olive and wheat; Terral & Arnold-Simard, 1996; Willcox, 2013) with early diffusions at a wide scale beyond the areas of origin of CWR **(Figure 2.2.5)** (see also Amazonian examples in **Box 2.3**). The same is also true in animal domestication, where complex evolutionary and ecological processes along with human selection have shaped the diversity and distribution of domestic animals (Larson & Fuller, 2014; Larson *et al.*, 2014) with the current distributions being much wider than original centres of origin.

Another large component of agrobiodiversity underpins other material and non-material contributions (fodder, fuel, fibres, etc.); (Diazgranados *et al.*, 2018; SOTWP, 2016); for example, there are at least 28,000 plant species that are currently recorded as being of medicinal use (Allkin *et al.*, 2017). Analysis of the distribution of these categories of plants indicates that the vast majority of them have overlapping and distinctive global ranges (see chapter 3; **Figure 2.2.6**; Allkin & Patmore, 2018; Diazgranados *et al.*, 2018), yet some of the highest concentrations of medicinal plant species appear to occur in regions outside of formally designated biodiversity hotspots.

Figure 2 2 5 **Origins and primary regions of diversity of agricultural crops. Source: Khoury *et al.* (2016).**

Box 2 3 **The contemporary globalization of native Amazonian and American plants.**



This map shows the current global centres of production (in tons) of key crops that originated from native American and Amazonian plants (Beaufort, 2017). Some important Amazonian crops, such as manioc and rubber, are not displayed.

The map highlights that many crops originating from agrobiodiverse regions are now used well beyond their centres of origin and domestication; and that the Amazon – often portrayed as the ultimate example of "pristine forest" – is actually a hugely important centre of domesticated nature, contributing significantly to the global agricultural economy.

One of the most globally widespread domesticated Amazonian plant genera is *Capsicum* (pepper; species *annum*, *chinense*, and *pubescens*). Other examples from the Amazon include pineapple *(Ananas comosus)*, papaya *(Carica papaya)* and peanuts *(Arachis hypogeae)*, which originated in South-West Amazon rainforest. Cocoa is also another globally important plant, which has at least ten different domesticated indigenous varieties scattered across the Amazon rainforest. Many of these cocoa varieties, as with dozens of other varieties of seeds and cultivars, are still managed by local traditional and indigenous groups in the Amazon. (Sources: Beaufort, 2017; FAO, 2014a)

2.2.3.5 Species populations

A measure of the abundance and distribution of a species' population is an important facet of nature to determine because this can significantly influence the level of ecosystem service provision (Luck *et al.*, 2003). For example, in agricultural landscapes where populations of local native vegetation provide important foraging and nesting habitats for pollinators, a distance of <2km between populations can mean that some fields are too far from nests to receive pollinator visits thus significantly reducing pollination services (Luck *et al.*, 2003; Nogué *et al.*, 2016). It is also an important measure to understand because species with naturally small ranges and populations tend to be more vulnerable to extinction, and the fact that a species, before going extinct, goes through a strong reduction in population size; and because sometimes range is often used as a measure of extinction risk (see Section 2.2.4).

The great majority of animal and plant species have small geographic distributions, many being found only across a very small proportion of the world's surface (e.g., **Figure 2.2.2D**; Orme *et al.*, 2006)). Species also differ in the population density (numbers per unit area or volume). This can be because of ecological and life history factors such as fecundity, trophic level and body size. For example, larger species tend to be less abundant locally, regionally and globally (White *et al.*, 2007). Population sizes of all species can also fluctuate naturally over time and space in response to natural changes in the abiotic environment and species interactions (e.g., Chisholm *et al.*, 2014; Inchausti & Halley, 2001): as a general rule, species' abundance will tend to be

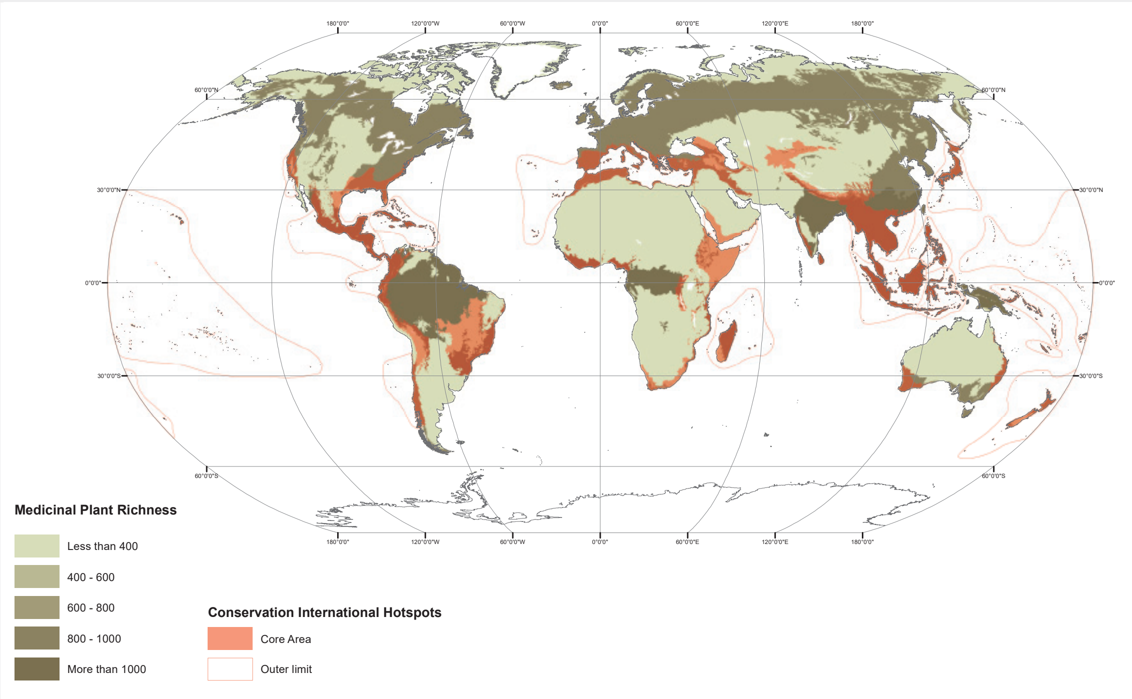


Figure 2 2 6 **Mean medicinal plant species (per 2° grid cell) in each natural unit of analysis (Allkin *et al.*, 2017; Diazgranados *et al.*, 2018).**

Also indicated are Conservation International's biodiversity hotspots. Acknowledgement and Source of map: Samuel Pironon and Ian Ondo, Department of Biodiversity Informatics and Spatial Analysis, Kew, Royal Botanic Gardens.

higher at places and times with more resources and fewer natural enemies. This is particularly true on the deep sea floor where abundances tend to be low even though species richness is high (Ramirez-Llodra *et al.*, 2010).

2.2.3.6 Organismal traits

Traits refer to the structural, chemical and physiological characteristics of plants and animals (e.g., body size, clutch size, plant height, wood density, leaf size or nutrient content, rooting-depth) that are related to the uptake, use and allocation of resources. Global variations in traits reflect the combined influence of abiotic (climate, geology, soils) and biotic variables (**Figure 2.2.2E**; Simard *et al.*, 2011) and can often mediate the relationship between organisms and their environment, thus dictating the resilience of biodiversity to environmental change (Willis *et al.*, 2018). Many traits show consistent patterns of within-species geographic variation; for example, most mammalian and avian species show larger body size in cooler regions (Meiri & Dayan, 2003; Olsen *et al.*, 2009). Similarly, leaf area and plant height become reduced in cooler regions. An understanding of traits is important for both biodiversity conservation and determining NCP.

First, traits directly affect the ability or otherwise of plants and animals to respond to environmental perturbations including land-use change, climate change, pests and pathogens and this in turn directly affects their conservation potential. When a community of organisms faces a particular driver of change, its responses will be therefore strongly mediated by the set of traits in the community and how variation in those traits is distributed within and among species and populations (e.g., Díaz *et al.*, 2013; Hevia *et al.*, 2017; Suding *et al.*, 2008). For example, in a global assessment on plant traits (Willis *et al.*, 2018), species with a less dense wood and shorter roots were less able to withstand intervals of drought than those possessing these traits. The same is also true for animals. In a recent study on global terrestrial mammals, for example, those species not possessing traits adapted to burrowing and/or requiring a specialized diet were less resilient to climate change (Pacifici *et al.*, 2017). There are also similar studies of traits of marine organisms to again indicate that certain traits provide greater resilience to environmental change (Costello *et al.*, 2015).

Second, organismal traits provide a critical link to biological functions that underpin the delivery of many important societal benefits (De Bello *et al.*, 2010; Diaz *et al.*, 2006; Lavorel, 2013). These include food and timber (quality and yield), pollination services, carbon sequestration, and soil nutrient quality and retention (De Bello *et al.*, 2010). Understanding variation in traits which enable resource security and supply particularly in the face of environmental change will become increasingly important in the future (Willis *et al.*, 2018). Yet despite their importance, still very little is known about the global distribution of traits in most taxonomic groups; e.g., a recent estimate suggested that only 2% of documented terrestrial plant species have associated trait measurements (Jetz *et al.*, 2016).

2.2.3.7 Genetic composition

Diversity in genotypes within and between species ultimately underpins variation among plants and animals, wild and domesticated, and thus provides the essential building blocks that underpin NCP. A diverse gene pool is also critical to provide resilience to disease, climate change and other environmental perturbations both in wild and domesticated populations. Understanding the diversity and distribution of global genetic resources is therefore of critical importance and has been identified as one of the most essential biodiversity variables to monitor in order to understand the health of the planet (Steffen *et al.*, 2015b).

Factors responsible for global patterns of genetic diversity are complex and are the result of evolutionary and ecological processes occurring across multiple timescales (Schluter & Pennell, 2017). However, some generalized patterns are apparent in animals. For example, a recent study that examined genetic diversity within 4600 mammalian and amphibian species at a global scale, demonstrated a broad latitudinal gradient with higher values in the tropical Andes and Amazonia (**Figure 2.2.2F**; Miraldo *et al.*, 2016). Other regions with high genetic diversity include the subtropical parts of South Africa for mammals and the eastern coast of Japan for amphibians. In temperate regions, western North America contains high level of genetic diversity, coinciding with high levels of mammalian species richness. In another recent study, examining genetic diversity of 76 animal species with global distributions, species traits related to parental investment and reproductive rates were also found to significantly influence genetic diversity – short-lived generalist species with high reproductive rates tend to have much higher levels of genetic diversity. Thus slow-living specialists have a much lower genetic diversity and are possibly therefore more vulnerable to environmental perturbations (Romiguier *et al.*, 2014).

A global understanding of patterns of genetic diversity in other groups (e.g., plants, marine organisms) is largely lacking although there are many excellent regional-scale studies indicating complex patterns resulting from processes occurring over millions of years (see Schluter & Pennell, 2017 for a review) and gene pools associated with crop wild relatives (see above).

Policy decisions can be tailored to enhancing adaptive evolution of species that are beneficial (e.g., keystone species or species with important benefits to people) and reducing the adaptive evolution of species that are detrimental (e.g., pests, pathogens, weeds). This topic is discussed in **Box 2.6** (Rapid evolution) in section 2.2.5.2.5.

2.2.4 CONTRIBUTION OF INDIGENOUS PEOPLES AND LOCAL COMMUNITIES TO THE CO-PRODUCTION AND MAINTENANCE OF NATURE

Indigenous Peoples and Local Communities (IPLCs), whose customary land encompasses approximately 50% of the global land area (Oxfam *et al.*, 2016) but see problems of mapping in chapter 1), often consider humans as an element of nature, with reciprocal exchanges between humans and non-humans that lead to nurturing and co-production.

It is important to emphasize that what has often been traditionally seen from a scientific or romantic perspective as untouched nature or wilderness is often the product of long-term use by IPLCs (e.g., the Kayapo cultural forests; Fairhead *et al.*, 1996; Posey, 1985; Willis & Birks, 2006). As wilderness areas cover an estimated 23% of land and are core to nature conservation (Watson *et al.*, 2016), a careful re-examination of cases based on long-term paleoecological and human historical records may help to overcome this controversy.

Although global studies that compare the status of biodiversity inside versus outside IPLC areas are limited, a large fraction of terrestrial biodiversity is found on IPLC land" (Sobrevila, 2008; Garnett *et al.*, 2018; Gorenflo *et al.*, 2012). Whilst this figure remains an estimate until there is a more complete documentation of areas managed and/or held by IPLCs (through efforts such as the Global Registry of ICCAs) and increased inclusion of diverse governance types in the World Database on Protected Areas (Corrigan *et al.*, 2016). However, such a high estimate is not unrealistic, given that at least a quarter of the global land area is traditionally owned, managed, used or occupied by Indigenous Peoples, including approximately 35 per cent of the area that is formally protected and approximately 35 per cent of all remaining terrestrial areas with very low human intervention (Garnett *et al.*, 2018; see also http://www.landmarkmap.org/ and chapter 1); and assuming that most rural populations pursuing small-scale non-industrial agriculture and forest management belong to 'local communities' adapted to local conditions.

It has also been noted many times that global patterns of biological diversity and cultural diversity seem not to be independent. However, while the overlap between cultural (e.g., linguistic) and biological diversity at the global scale is undeniable (Maffi, 2001; Stepp *et al.*, 2004), likely reasons for co-occurrence of linguistic and biological diversity are complex and less well known (Moore *et al.*, 2002). Co-occurrences may be due, for example, by the longevity of local occupation, isolation caused by terrain, and specific (e.g., tribal) social structures and appear to vary among localities. Nevertheless, strong geographic concordance argues for some form of functional connection (Gorenflo *et al.*, 2012); this is something that requires further biocultural explorations (see Section 2.2.6.3 for more details; Gavin *et al.*, 2015).

There are many cases in the world where IPLCs 'contribute' to nature by co-producing genetic diversity, species and ecosystem diversity through 'accompanying' natural processes with anthropogenic assets (knowledge, practices, technology; Berkes, 2012; Forest Peoples Programme *et al.*, 2016b; Posey, 1999). IPLCs often manage inland and coastal areas based on culturally specific values and worldviews, applying principles and indicators like health of the land, caring for the country, and reciprocal responsibility with the goal of promoting ecosystem health, respect and integrity (Berkes, 2012; Lyver *et al.*, 2017; Posey, 1999). However, unsustainable indigenous practices are becoming increasingly common, e.g., the 'empty', 'silent' forests (Redford, 1992) and pasture degradation (see also 2.2.5.1-2-3, chapter 3 (3.2.4, 3.3.3) and chapter 4 (4.4.1)). Changes in these areas are also often driven by changes in land management by governments and corporations (White *et al.*, 2012), and the proportion of areas still managed by IPLCs and/or according to indigenous and local concepts is decreasing (Borras Jr *et al.*, 2011).

Case studies below show where the nature that contributes to people has been co-produced by local people.

2.2.4.1 Co-production of cultural landscapes with high ecosystem heterogeneity

High-diversity cultural landscapes (Agnoletti, 2006) and Socio-Ecological Production Landscapes and Seascapes (SEPLS, satoyama-initiative.org), which often comprise a complex mosaic of forested areas, wet, irrigated and dry places, and coastal habitats, can provide a richness of food, fodder, timber, medicinal plants to local communities. Such landscapes have a long history of human-nature co-production. For example, the Mediterranean pasture or crop and oak agro-sylvo-pastoral systems (known as Dehesa in Spain, Montado in Portugal), olive and fig agro-sylvo-pastoral systems, holm oak-truffle woods, chestnut rural forests, and argan agroecosystems are a number of human-nature co-production systems that are known to host a rich open habitat flora with diverse ecotones and a high level of landscape heterogeneity (Aumeeruddy-Thomas *et al.*, 2016, 2012; García-Tejero & Taboada, 2016; Lopez-Sanchez *et al.*, 2016; Michon, 2011).

2.2.4.2 Development of species-rich semi-natural ecosystems of wild species

In cultural landscapes where people have actively changed the local disturbance regime, species-rich habitats can develop. Some of these ecosystems, made up of wild native species, became local 'hotspots' of diversity. These include for example, the European hay meadows (see **Box 2.4** below) which have replaced many broad-leaved and coniferous forests in mountainous and boreal regions, and which were purposefully developed by local communities (Babai & Molnár, 2014). These meadows are among the most species-rich grasslands on Earth at several small spatial scales (up to 60–80 vascular plant species per 16 m^2; Wilson *et al.*, 2012). The species richness of these hay meadows is correlated with the longevity and continuity of a more or less stable extensive traditional management spanning thousands of years (Merunková & Chytrý, 2012; Reitalu *et al.*, 2010; Zobel & Kont, 1992).

2.2.4.3 Creation of new ecosystems with a combination of wild and domestic species

In many regions of the world Indigenous Peoples and Local Communities have combined wild and domesticated species in their agroecosystems to create new, often highly diverse ecosystems. These farming systems often sustain communities of diverse plant and animal species with increased synergy (in production and resilience). For example, IPLCs have developed multi-species tropical forest gardens in Kebu-talun and Pekarangan in West Java (Christanty *et al.*, 1986), rotational swidden agriculture in Thailand (Wangpakapattanawong *et al.*, 2010) and see **Box 2.4** below). In many of these locally developed traditional agroforestry systems trees, crops and/or livestock associations (Michon *et al.*, 2000; Wiersum, 2004) differ according to biocultural, social, economic and political contexts. In addition, the interaction between wild and cultivated components (often called rural forests) that occur in this agroforestry systems can result in hybridization and have been suggested as a major driver of tree domestication across the planet (Aumeeruddy-Thomas & Michon, 2018; Aumeeruddy-Thomas, 1994; Genin *et al.*, 2013; Michon, 2015).

In wetland ecosystems, another combination of wild and domestic species that occurs is the rice-fish-duck culture in China (Xue *et al.*, 2012). In addition, flooded plains across the tropics (e.g., since pre-Columbian times in Bolivia and French Guyana, also contemporary Africa) have agroecosystems based on the construction of large human-made mounds for cultivation. These are known to have brought into these flooded plains a rich agricultural biodiversity, while hosting also a large diversity of soil diversity and insects that benefit from these elevated terrestrial parts of the landscapes (McKey *et al.*, 2016). Human-made oases or other highly modified ecosystems developed by local communities, can enhance natural processes as well as biological diversity (Tengberg *et al.*, 2013).

2.2.4.4 Contributing to agrodiversity by selection and domestication

Domestication is an ongoing process that has been occurring for at least the past 20,000 years on Earth. Indigenous Peoples and Local Communities maintain many local varieties and breeds of plants, animals, and fungi and thus facilitate adaptations to the changing social-ecological environment. Domestication is about selection of specific traits, and their integration into social-ecological niches that often differ from their original habitats. This process has occurred over millennia, since the Epipaleolithic (ca. 20 000–5 000 years ago) in the Mediterranean region and at similar periods in Papua New Guinea, Mexico, South America, and Central Asia (Castañeda-Álvarez *et al.*, 2016; Ellis *et al.*, 2018; Larson & Fuller, 2014).

Local plant and animal landraces (domesticated, locally adapted, traditional varieties and breeds) may either correspond to areas of origin or be a consequence of human-assisted dispersal across the planet. For instance, the pre-Columbian travel of sweet potato from South America where it was domesticated to the Pacific islands (Roullier *et al.*, 2013a, 2013b), ultimately reached Papua New Guinea where it became a very important staple food and also diversified as a result of isolation from its area of origin, new ecological conditions and selection by humans (see **Box 2.3**). This effect of diffusion and genetic isolation, adaptation and selection are clearly a co-production resulting from Indigenous Peoples and Local Communities manipulating ecological and biological evolutionary processes. Domestic animals have evolved far from their wild relatives' origin and represent another example of joint production linked to selection by people and adaptation to local environments. For example, there is an estimated ca. 800 local breeds of domesticated cattle, although the true numbers are incompletely known (FAO, 2015b).

2.2.4.5 Enhancement of the natural resilience through traditional management

Many traditional resource management systems are 'designed' to be resilient by IPLCs, thus enabling social-ecological systems to collectively respond or adapt to changes (Berkes *et al.*, 1998). Activities that are promoted to enhance natural resilience include for example, the

Box 2 4 Two cultural landscapes where anthropogenic processes enhance biodiversity.

Embedded in the cultural landscape in Gyimes (Carpathians, Romania), these meadows were created by local Hungarian Csángó people to provide valuable hay and are now extremely species-rich semi-natural ecosystems (Section 2.2.4.2). Meadows are managed based on a deep understanding of local ecological processes (e.g., hayseed is gathered in the barns and spread onto hay meadows to increase hay quantity and quality, (Babai *et al.*, 2014, 2015). (Photo: Dániel Babai)

This socioecological production landscape has created new ecosystems with many wild and domestic species (Section 2.2.4.3), with rotational farming developed and managed by Karen people in Thailand with traditional co-creation techniques (an example for 2.2.4.3). *"A system that speaks to sustainability and livelihood security". "We select places for cultivation by listening to the sound of a stick hit to the soil in soft-wood and bamboo forests able to resprout while we avoid areas with large trees, having certain birds and mammals, and that are close to streams." "We seed not only rice but many kinds of vegetables and vibrant coloured flowers believed to keep insects and birds away."* Source: Global Assessment face-to-face consultation with Kriengkrai Chechuang, Thailand. (Photo: Pernilla Malmer)

protection and restoration of natural and modified ecosystems, the sustainable use of soil and water resources, agro-forestry, diversification of farming systems, crop development (e.g., stress-tolerant crops) and various adjustments in cultivation practices (Barrios *et al.*, 2012; Emperaire, 2017; Mijatović *et al.*, 2012). Farmers often utilize the diverse ecology of different crops to add synergy (such as nitrogen fixing plants, trees for shade, animals for fertilizing soils or rice fields). Such systems can diffuse risks caused by extreme climate events (e.g., floods, drought), pests or pathogens. Traditional knowledge of the ecology and cultivation of crops is combined with social practices, such as exchange networks, including seed exchange networks (Coomes *et al.*, 2015; Thomas & Caillon, 2016; Wencélius *et al.*, 2016) to increase a farmers' capacity to find adequate landraces either to adapt to changing markets or changing climate.

2.2.4.6 Increase local net primary biomass production at the landscape scale

IPLCs often increase local biomass production by, for example, rotational farming and disturbance regimes (see Section 2.2.4.2 above). Examples of this type of activity includes for example, creation of rich berry patches (dominated by *Vaccinium* spp. and other berries) in boreal forests by regular burning (Davidson-Hunt, 2003; Johnson, 1994). In addition, prescribed regular burnings and community-based fire management of dry grasslands, forests and marshes can sometimes not only prevent larger fires that would damage local livelihoods, but they can also help the resprouting of herbaceous vegetation and restore habitat and landscape structure favourable for biodiversity (Miller & Davidson-Hunt, 2010; Pellatt & Gedalof, 2014; Russell-Smith *et al.*, 2009). The same is true for some properly executed grazing regimes by domestic livestock that are adapted to the local environment and are able to prevent overgrazing (Molnár, 2014; Tyler *et al.*, 2007).

In other cases, Indigenous Peoples and Local Communities – unintentionally – maintain high levels of prey animals (e.g., sheep) that 'provide' an additional food source, which in turn are important for maintaining iconic predators (lion, leopard, wolf, bear; Casimir, 2001; Mertens & Promberger, 2001). Similarly, fruit gardens 'provide' food for frugivorous mammals when forest fruits are scarce (Moore *et al.*, 2016) and thus contribute to the protection of threatened species by this extra food (Siebert & Belsky, 2014).

2.2.4.7 Contribution to biodiversity by sustaining and protecting ecosystems of high conservation value from external users

IPLCs sustain naturally developed or modified ecosystems (such as the ones featured in the previous sections), and prevent species and ecosystem loss in these areas, for example by restricting access, and thus preventing unsustainable practices by outsider users (e.g., legal and illegal logging, mining, poaching, overexploitation of fisheries; see ICCAs, OECMs; Berkes, 2003; Borrini-Feyerabend *et al.*, 2004; Corrigan *et al.*, 2016; Govan, 2016; Nepstad *et al.*, 2006; also see chapters 3 and 6).

Additionally, some threatened species and some areas have strong cultural and/or spiritual significance (sacred species and sites) or are important for communities' well-being (e.g., medicinal plants, mental health) and thus have been actively conserved by communities through totem restrictions, hunting and harvesting taboos, sacred groves, rivers and springs, total or temporal use restrictions or nurturing sources of ecosystem renewal (Bhagwat, 2012; Colding & Folke, 1997; Pungetti *et al.*, 2012). These social taboos are often 'invisible' and thus not recognized or accounted for in conventional conservation (Colding & Folke, 2001) though this is changing (Bennett *et al.*, 2017).

2.2.5 STATUS AND TRENDS IN NATURE

Nature has faced multiple drivers of change from human actions. Many of these drivers have accelerated rapidly (chapter 2.1). The same is true for many changes in nature. Indeed, for some facets of nature, the changes have accelerated so rapidly that as much as half the total anthropogenic change in the whole of human history may have taken place since the mid-20th century. This section first discusses pre-1970 trends in nature before discussing trends since 1970 alongside current status.

2.2.5.1 Pre-1970 trends in nature

Humanity developed the capacity for significant ecosystem engineering around 10,000 years ago, marking a major ecological transition in Earth's history. Since then, the cumulative effects of human activities on some aspects of nature have been dramatic (Boivin *et al.*, 2016; Erlandson & Braje, 2013; Smith & Zeder, 2013). Actions that increased the number of people the land can support have also caused species extinctions and changed species distributions, habitats and landscapes since the Stone Ages (Foley *et al.*, 2013; Pimm & Raven, 2000; Vitousek *et al.*, 1997).

Although the state of nature has changed constantly throughout Earth history, the scale and extent of changes

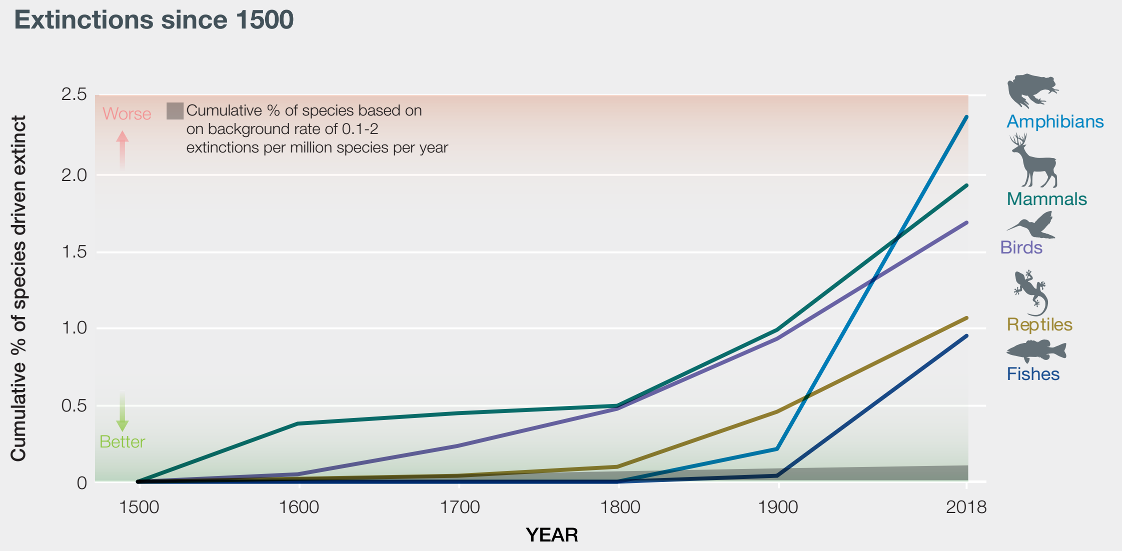

Figure 2 2 7 **Extinction rates per century since 1500 for vertebrate classes.**

Fishes includes bony fishes, cartilaginous fishes and lampreys. Values for Reptiles and Fishes are likely to be underestimates as not all species in these groups have been assessed for the IUCN Red List. The range of background rates of extinction (grey line) is based on 0.1- 2 extinctions per million species per year, following Ceballos et al. (2015) and references therein.
Source: Analysis of data in the IUCN Red List in September 2018.

driven by human actions have led to this human-dominated period in Earth history being commonly called the Anthropocene (Crutzen, 2002). From an ecological perspective, the Anthropocene may have begun in the late Pleistocene (Lyons *et al.*, 2016; Smith & Zeder, 2013). Human actions played a role (along with climate and other drivers) in the megafaunal extinction around the Pleistocene-Holocene boundary (Erlandson & Braje, 2013; Johnson *et al.*, 2017); this disappearance of large herbivores and predators dramatically affected ecosystem structure, fire regimes, seed dispersal, land surface albedo and nutrient availability (Johnson, 2002).

From the Late Pleistocene onwards, humans started to colonize and transformed most resource-rich landscapes on Earth (Erlandson & Braje, 2013). This near-global human expansion was followed by the Neolithic spread of agriculture across the world the centres of domestication (Section 2.2.3.4.3), driven by a set of long-term, complex and independent factors like demography, climate, human behaviour and resource imbalance (Zeder & Smith, 2009). This transformation to agriculture created highly modified production landscapes, caused significant land cover change (e.g., forest loss which triggered erosion and sedimentation in rivers and lakes), and spread new varieties and breeds of domesticated animals and crops as well as other (e.g., weed) species (Baker, 1991). These changes altered all Earth systems from the lithosphere and biosphere to the atmosphere. For example, expansion of paddy rice fields and pastoralism is thought to have increased atmospheric methane from as early as 4000 years ago (Fuller *et al.*, 2011).

All these changes increasingly concentrated biomass into human-favoured species (Barnosky, 2008; Williams *et al.*, 2015). Humans used fire for large-scale transformation of "savannas" (Archibald *et al.*, 2012), while diverse grazing regimes reshaped and expanded grasslands during the last 3000–7000 years. Improved seafaring since the mid-Holocene enabled colonization of even remote islands. Island ecosystems, with "naïve" species and low functional redundancy, often changed dramatically after human colonization (Rick *et al.*, 2013); e.g., two third of bird species native to Pacific islands went extinct between initial human colonization (after 1300 BC) and European contact (17th century) (Duncan *et al.*, 2013). Many exploited species worldwide have evolved to be smaller (Fitzpatrick & Keegan, 2007; Jørgensen *et al.*, 2007).

European colonialism from 1500 to early 1800s fundamentally transformed pre-existing indigenous cultural landscapes, with deforestation for monocrop plantations and the spread of invasive alien species (Dyer *et al.*, 2017). Populations of fur animals, fishes and whales were overexploited for the new global market (Lightfoot *et al.*, 2013; Monsarrat *et al.*, 2016; Rodrigues *et al.*, 2018).

Spread of global commerce mostly from Europe, together with the spread of the European naturalistic worldview, had a huge impact on local human-nature relations and hence on land use (Lightfoot *et al.*, 2013), resulting for example in the spread of timber-oriented forest management (Agnoletti, 2006). Global forest cover decreased for millennia (Pongratz *et al.*, 2008), and large trees were lost from many areas well before the mid-20th century (Lindenmayer *et al.*, 2012; Rackham, 2000).

Marine defaunation started only a few hundred years ago and may have been less severe than defaunation on land (Dirzo *et al.*, 2014; McCauley *et al.*, 2015). Though few marine species are known to have gone globally extinct (Webb & Mindel, 2015), many became ecologically or commercially extinct with the onset of commercial and industrial scale exploitation, the most threatened animals being those that directly interact with land (McCauley *et al.*, 2015).

The Industrial Revolution in Europe, and the growth of populations and cities that it enabled, accelerated impacts on biodiversity. For example, some habitats have lost >90% of their area since 1800 especially in Europe (Biró *et al.*, 2018) and North America. The Green Revolution after World War II drove further agricultural intensification, causing a rapid decline of species of agricultural habitats and the spread of invasive species, and further increasing the proportion of net primary production taken by humanity (Krausmann *et al.*, 2013). Extinction rates rose sharply in the 20th century for all taxonomic groups for which a robust assessment can be made **(Figure 2.2.7)**.

2.2.5.2 Trends in nature since 1970 and current status

The status and recent trends seen in terrestrial, freshwater and marine ecosystems clearly show that humanity is a dominant global influence on nature. This assessment of current status and trends since 1970 synthesizes over 50 quantitative global indicators, covering an unprecedentedly diverse set of facets of nature (because nature is too complex for its trends and status to be captured by one or a few indicators: Section 2.2.3), together with recent meta-analyses, reviews and case studies, organized into Essential Biodiversity Variable classes (Section 2.2.3.1). Attribution of changes to drivers is considered in Section 2.2.6. below.

The linkages among different aspects of nature in ecosystems mean that trends may differ systematically among EBV classes. For instance, forest loss causes local extinction of forest-adapted species, but this species may accelerate once the fraction of natural habitat remaining goes below 30% (Banks-Leite *et al.*, 2014; Ochoa-Quintero *et al.*, 2015). Likewise, local declines in species richness can drive nonlinear declines in ecosystem function, with function initially declining less rapidly than species richness (Cardinale *et al.*, 2012; Hooper *et al.*, 2012).

Even within an EBV class, indicator trends are likely to vary by much more than their statistical margins of error. One reason is that some components of nature are expected to be more sensitive than others – e.g., habitats such as warm-water coral reefs that have narrow environmental tolerances – so indicators reporting on them may show the steepest trends; they are in effect the 'canaries in the coal mine' that provide the first clear evidence that drivers are reshaping nature. By contrast, other indicators try to reflect the status of nature more broadly, e.g., all species within a large taxonomic group such as mammals; these indicators are also important because the broader state of nature underpins consistent delivery of many NCP, especially over longer time scales, across larger areas, and in the face of ongoing drivers (Cardinale *et al.*, 2012; Mace *et al.*, 2012; Oliver *et al.*, 2015; Steffen *et al.*, 2015b; Winfree *et al.*, 2018). A second reason for variation is that some indicators use more coarse-grained data than others. For example, species' extinction risk is measured on a relatively coarse spatial and temporal scale (the IUCN Red List categories), so indicators synthesizing these data may miss gradual declines of abundant, widespread species, which indicators based on species' abundances may capture (Butchart *et al.*, 2005). Consequently, indicators of species populations based on species' extinctions and extinction risk are here considered separately from those based on species' abundances or distributions. A third reason is that some trends might only be apparent at one spatial scale. Because this is particularly true for community composition (Jarzyna & Jetz, 2018; McGill *et al.*, 2015), trends within this EBV class are discussed at three different scales: local (e.g., the set of species in a small area of the same habitat type), regional (e.g., the set of species in a country or large grid cell), and the differences between local communities within the same region.

Where possible, each indicator is expressed in two ways. First, the recent rate of change shows how quickly it is changing over time; the average per decade change in the indicator is expressed as a percentage of the estimated value for 1970 (or, if later, for the beginning of the time-series). Second, the current status is shown as a percentage of the inferred or estimated natural baseline level (i.e., the value in a pristine or at least much less impacted – e.g., pre-industrial – world), showing how much remains (see **Figures 2.2.8–2.2.20**). Most indicators are designed such that a larger value equates to there being more of the focal component of nature, but some are the other way around (e.g., numbers of species extinctions). Here, for ease of comparisons, such reverse indicators are rescaled so that values are larger when there is more nature (note that more is not always better – for instance, a rise in the number of invasive alien species is not desired).

For some indicators that can be mapped at sufficient spatial resolution, the status and trend are also shown within the hotspots of narrowly-distributed species (mapped in **Figure 2.2.3**), and within the areas mapped (Garnett *et al.*, 2018) as indigenous lands (mapped in Figure SPM5); in the plots below, these have "hotspots" or "indigenous lands" as part of the indicator name. Some other indicators are also subsets (e.g., the persistence of pollinating vertebrates is a subset of the persistence of all terrestrial vertebrates). All subsets are shown as unfilled symbols in the plots that follow; to avoid 'double counting', they are omitted when calculating averages across indicators. The Supplementary Materials define and explain each indicator, its source and how it has been treated here, along with (where possible) how the natural baseline was estimated and plots of how the indicators has changed over time. In this section, italics are used to highlight indicators plotted in the figures for each Essential Biodiversity Variable class. Chapter 3 considers many of the same indicators, sometimes with very different presentation and analysis reflecting that chapter's different scope. Indicators that are designed to report on trends in nature directly responsible for particular classes of NCP are developed and presented in chapter 2.3.

2.2.5.2.1 Ecosystem structure

(N.B. Italics denote indicators plotted in **Figure 2.2.8**)

Most global indicators show a net deterioration in the structure (i.e., extent and physical condition) of natural ecosystems since 1970 of at least 1% per decade **(Figure 2.2.8A)**, and indicators have fallen to by almost half of their natural baseline levels (to a median of 53.2%: **Figure 2.2.8B**). There can be no doubt that human actions have radically changed, and are continuing to change, ecosystem structure – especially in sensitive ecosystems – across much of the world. Given that ecosystem structure sets the stage for ecological, evolutionary and social-ecological processes, these changes potentially jeopardize nature's ability to deliver many societal benefits. The indicators that can be estimated within the terrestrial hotspots of rare species have lower status and steeper declines there than across the globe, which is particularly concerning for biodiversity conservation; conversely, these indicators have better current status and slower declines in indigenous lands than globally.

Indicators of coastal and shallow marine ecosystems are already at low levels and are continuing to decline particularly rapidly (e.g., seagrass meadow area Waycott *et al.*, 2009; mangrove forest area Hamilton Stuart & Casey, 2016; live coral cover on reefs Eddy *et al.*, 2018; Ortiz *et al.*, 2018). The declines have direct societal implications. For example, coastal protection habitats (Ocean Health Index, 2018) protect against storm surges and can elevate coastlines in step with rising sea level (Spalding *et al.*, 2016),

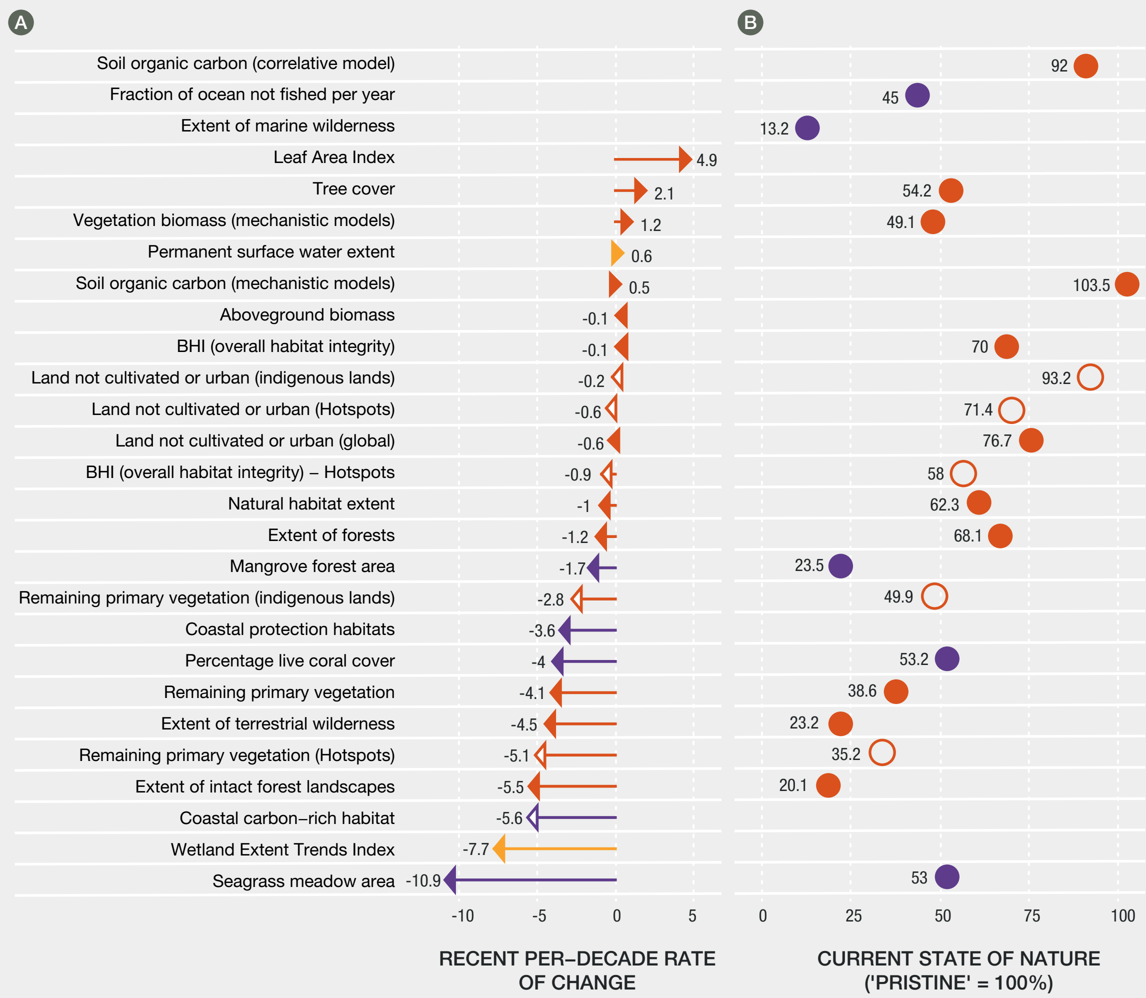

Figure 2 2 8 **Global indicators of natural ecosystem structure.**

Marine indicators are in purple, terrestrial in orange and freshwater in yellow. Solid symbols are used for overall indicator values, whereas hollow symbols show the indicator is a subset of another. A Trends, shown as the average per-decade rate of change since 1970 (or since the earliest post-1970 year for which data are available), ordered by rate of change. Most indicators show declines (left-pointing arrows; 14/17 overall indicators) and the median change overall is -1.1% per decade. B Estimated current status relative to a pristine or at largely pre-industrial baseline. On average, status is only just over half of the baseline value (median = 53.2%). Note that, even though tree cover has a positive trend in recent decades, earlier declines mean it is still well below its natural baseline. Some indicators provide only either rate or status so appear in only one panel. The Supplementary Materials provide detailed information and full references for each indicator, including subsets.

and coastal carbon-rich habitats (Ocean Health Index, 2018) can act as carbon sinks.

Other sensitive ecosystems also combine rapid decline with low levels relative to historical baselines. For example, only 13% of ocean (including almost none of most coastal ecosystems) (Jones *et al.*, 2018) and 23% of land (most of it inhospitable or remote; Watson *et al.*, 2016) are sufficiently free of obvious human impacts to still be classed as *wilderness* (and see 2.2.4 for discussion of likely human influence even there). *Intact forest landscapes* (defined as areas of forest or natural mosaics larger than 500 km^2 where satellites can detect no human pressure) continue to decline rapidly in both rich and poor countries, and especially in the Neotropics, due to industrial logging, agricultural expansion, fire and mining (a loss of 7% between 2000 and 2013; Potapov *et al.*, 2017). Estimates of the fraction of land that can still be viewed as 'natural' rather than anthropogenic range from under 25% (Ellis & Ramankutty, 2008) to over 50% (FAO, 2014a; Sayre *et al.*, 2017), depending on how 'natural' is defined. Just 39% of land area is still classed as *primary vegetation* (i.e., has never been cleared or regularly grazed; Hurtt *et al.*, 2018), putting many species of habitat specialists at potential risk (Brook *et al.*, 2003; Matthews *et al.*, 2014). The *Biodiversity Habitat Index* (Hoskins *et al.*, 2018), which recognizes that modified habitat still supports some biodiversity, estimates the current global integrity of terrestrial habitat for native biodiversity to be 70% of its original natural level. The *Wetland Extent Trend Index* is declining rapidly (Dixon *et al.*, 2016) and as much as 87% of the natural wetland in 1700 was lost by 2000 (Davidson, 2014) (see also 2.2.7.9). The slight net increase in the *extent of permanent surface water* masks extensive turnover: 13% of the area of permanent water in the 1980s had been lost by 2015, outweighed by a 16% expansion largely from new reservoirs (Pekel *et al.*, 2016).

Although *land neither cultivated nor urban* (based on satellite data and including grazing land; ESA, 2017) has decreased only slowly since 1992, much more rapid declines are seen in some units of analysis (temperate grasslands, -2.5%; tropical and subtropical forests, -1.3%; see Supplementary Materials 2.2.2.9). Some regions have also seen particularly rapid land cover change: between 2001–2012, the Arctic saw a 52% increase in the extent of forest, 19% increase in wetland and a 91% decrease in barren ground (Shuchman *et al.*, 2015).

Another indicator with marked regional variation is *aboveground biomass* **(Figure 2.2.9)**: globally, it fell by only ~ 0.2% (< 1 PgC) between 1990 and 2012 (with a dip in the mid-2000s), but tropical forests saw a fall of ~ 5 PgC (especially in Amazonia and Southeast Asia) while boreal and temperate mixed forests saw a rise of ~ 2.3 PgC (Liu *et al.*, 2015). Land-use change and intensification have reduced *vegetation biomass* – of which trees are the main component – to below 50% of the level expected if there were no human land use, mostly before 1800 (Erb *et al.*, 2018), with model-ensemble estimates (Le Quéré *et al.*, 2018) showing an upward trend since 1970 driven by CO_2 fertilization, climate change and regrowth after previous land-use change.

The indicators relating to forest structure suggest that deforestation has gone beyond the precautionary 'safe limit' for land-system change proposed in the Planetary Boundaries framework (Steffen *et al.*, 2015b). That framework argues that reduction of forests below 75% of their natural extent risks dangerous reduction in biotic regulation of global climate, though there is uncertainty over exactly where the danger point lies (Steffen *et al.*, 2015b). The global area of *tree cover* (assessed from remote-sensing data; Song *et al.*, 2018) is estimated to be only 54.2% of the area at the dawn of human civilization, while current *extent of forests* (defined as having tree cover >10%, aggregated from national statistics; FAO, 2016a) is 68.1% of their pre-industrial extent. These values are 1250 million ha and 460 million ha, respectively, below the proposed safe limit; as a comparison, Brazil's area is 852 million ha.

Deforestation has slowed since its peak in the 1990s. The *extent of forests* fell markedly more slowly in 2005–2015 than in 1990–2005 (FAO, 2016a), and global *tree cover* has actually risen, by 2.6% per decade from 1982–2016 (Song

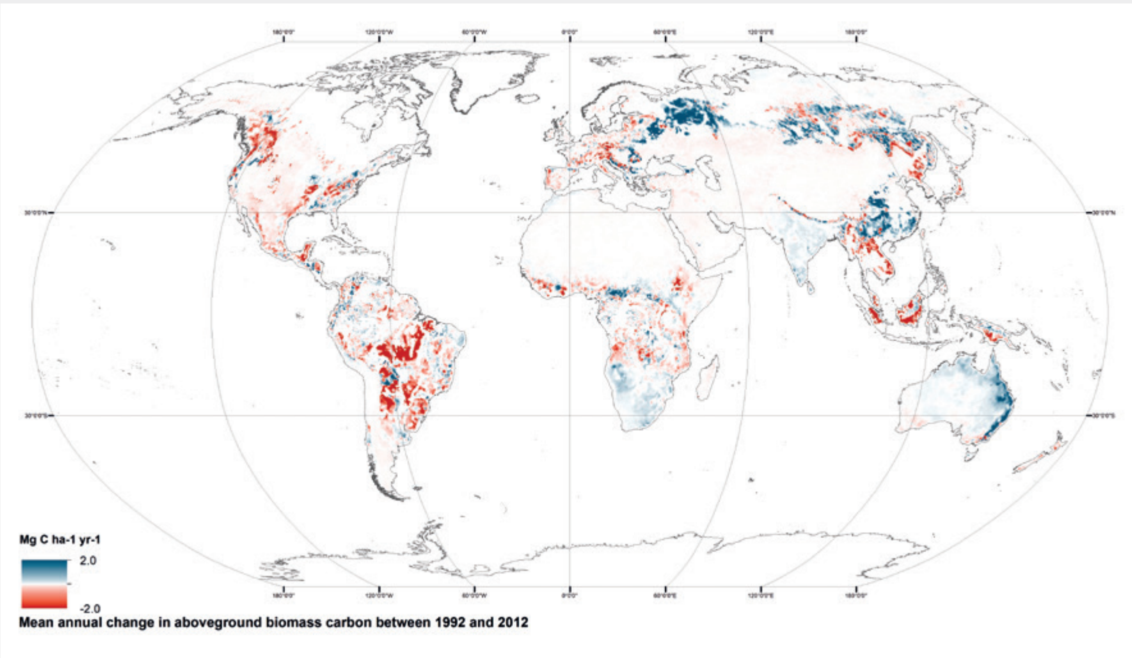

Figure 2 2 9 **Mean annual change in aboveground biomass from 1993 to 2012; data from Liu *et al.* (2015).**

et al., 2018). However, both indicators are still falling in the tropics while rising in temperate and boreal regions (FAO, 2016c; Song *et al.*, 2018); and approximately 15.3 billion trees are still being lost each year, through deforestation, forest management, disturbance and land-use change (Crowther *et al.*, 2015).

The rapid increase in *leaf area index* that is apparent **(Figure 2.2.8)** (the area of leaves per unit area of land) is largely driven by changes in north temperate latitudes where climate change has increased annual plant growth (Zhu *et al.*, 2013). Mechanistic models (Le Quéré *et al.*, 2018) infer that global *soil organic carbon* (see **Figure 2.2.8B**) now stands at 104% of the level in the 1860s; but an alternative correlative approach estimates that land use has reduced levels to 92% of their natural baseline (Van der Esch *et al.*, 2017). These diverging estimates could be partly reconciled if much of the loss caused by land-use change was before 1860; but more observation and modelling are needed.

For the indicators where we were able to make the comparison, ecosystem structure is on average less intact and declining more rapidly in the terrestrial hotspots of species rarity (as demarcated in Section 2.2.3.4.2) than across the world as a whole. Only 35.2% of their land area is still classed as *primary vegetation* and per-decade loss has averaged -5.1% of the 1970 level (the global figures are 39% and -4.1%, respectively). The corresponding values for *land neither cultivated nor urban* (ESA, 2017) in hotspots (71.7% and –0.6% per decade) are also worse than across the world as a whole (76.7% and -0.2%, respectively: **Figure 2.2.10**). The habitat integrity (*Biodiversity Habitat Index* (Hoskins *et al.*, 2018)) of these rarity hotspots is only 58%, much less than the overall global estimate of 70%.

By contrast, ecosystem structure is on average more intact and declining more slowly in indigenous lands than across the world as a whole. Nearly 50% of mapped indigenous land (Garnett *et al.*, 2018) is still *primary vegetation* (Hurtt *et al.*, 2018); and the rate of decline is only –2.8% per decade. Likewise, 93.2% of indigenous land (Garnett *et al.*, 2018) is *neither cultivated nor urban* (ESA, 2017), and this fraction is declining only a third as rapidly in indigenous lands as it is globally (-0.2% versus -0.6% per decade).

Knowledge gaps: There are few indicators for the structure of freshwater or marine ecosystems, especially in the

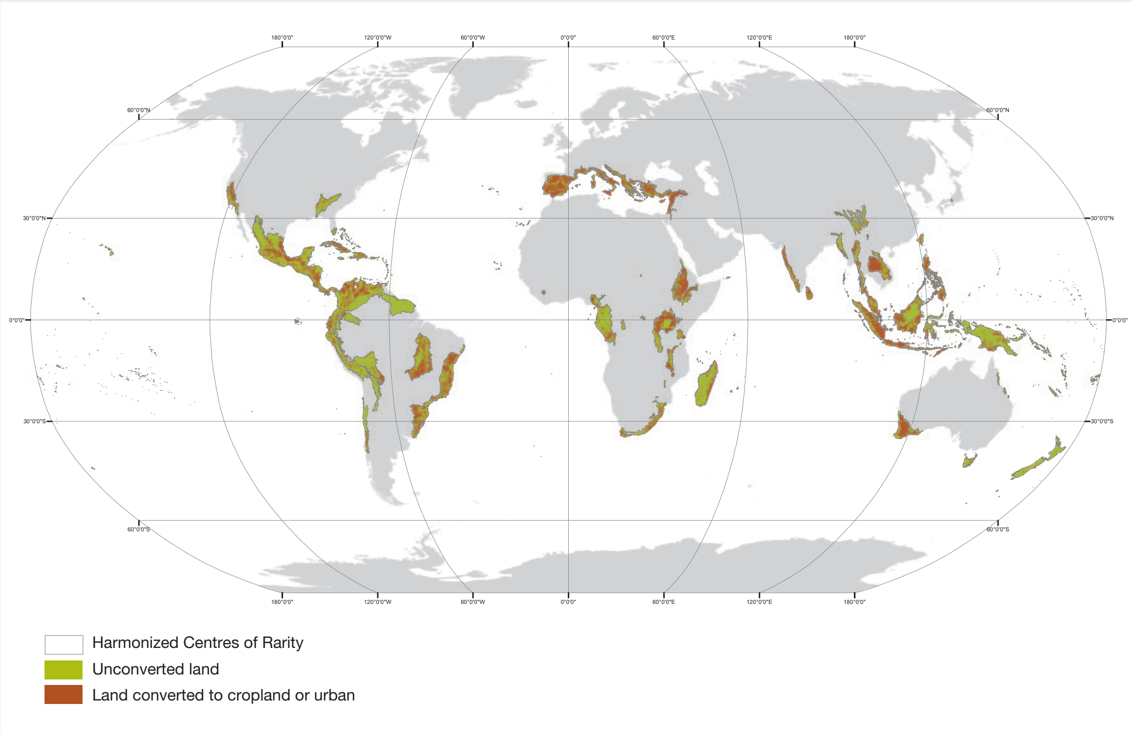

Figure 2 2 10 **Many terrestrial hotspots of endemic species (harmonized across multiple taxonomic groups as in Figure 2.2.3, Section 2.2.3.4.2) have experienced widespread conversion of natural habitat to cropland and urban areas, according to satellite-derived land-cover data (ESA, 2017).**

deep sea. Ecosystem condition is less well represented than ecosystem extent (because it is harder to measure consistently across space and over time), meaning that important degradation of ecosystem structure may be missed. For example, an estimated 35.9 Pg of soil was lost to erosion in 2012, 2.5% more than in 2001 (Borrelli *et al.*, 2017), with soil eroding from conventional agricultural landscapes far more rapidly than it is formed (FAO & ITPS, 2015). Land degradation – of which soil erosion is but one facet – is a global problem, affecting all land systems in all countries, but there is no quantitative consensus on its extent or trend (IPBES, 2018): e.g., estimates of the still undegraded fraction of the land surface range from 75.8% to 96.8% (Gibbs & Salmon, 2015). Estimates of the current global extent of grazing land also vary widely (Phelps & Kaplan, 2017; Prestele *et al.*, 2016).

2.2.5.2.2 Ecosystem function

(N.B. Italics denote indicators plotted in **Figure 2.2.11**)

Evidence suggests that rates of some fundamental ecosystem processes have accelerated greatly **(Figure 2.2.11)**. For example, the terrestrial *biomass turnover rate* – how quickly biomass is broken down and replaced – has nearly doubled on average; has increased more than tenfold in croplands and artificial grasslands; and has increase at least threefold in East and South Asia and Western, Eastern and Southern Europe (Erb *et al.*, 2016).

Two differently-estimated indicators of *terrestrial Net Primary Production (NPP)* – which forms the base of most ecological food webs and material NCP – suggest slightly different trends. An ensemble of process-based models (Le Quéré *et al.*, 2018) suggests terrestrial NPP has risen by 2.6% per decade since 1970 – though the trend is flat over the past decade – and is now nearly 30% higher than in the 1860s (the earliest decade modelled). These models all assume that rising atmospheric CO_2 boosts photosynthesis, but the magnitude of this CO_2 fertilization effect is highly uncertain (Wenzel *et al.*, 2016). In contrast, estimates derived instead from satellite data (Zhao & Running, 2010) suggest a less rapid (and not statistically significant) increase, over the much shorter time period for which the data are available (Wang *et al.*, 2012). The approaches agree, however, that the overall change masks wide spatial heterogeneity in the trend (**Figure 2.2.12**; Zhao & Running, 2010). *Marine NPP* (Behrenfeld & Falkowski, 1997) rose by 4.7% from 1998–2007.

Carbon sequestration from the atmosphere helps to slow climate change, making it another important ecosystem function to measure. The ensemble of process-based models suggest *terrestrial carbon sequestration* has recently been rising by 25% per decade and *oceanic carbon sequestration* by 29% per decade (Le Quéré *et al.*, 2018), despite a slight reduction in the *efficiency of the biological pump* (Cael *et al.*, 2017).

The annual amount of *NPP remaining in terrestrial ecosystems* after human appropriation (Krausmann *et al.*, 2013) is now around 86% its inferred natural baseline level (though only 64% in Asia). Its slow net change through history probably reflects a near-balance between

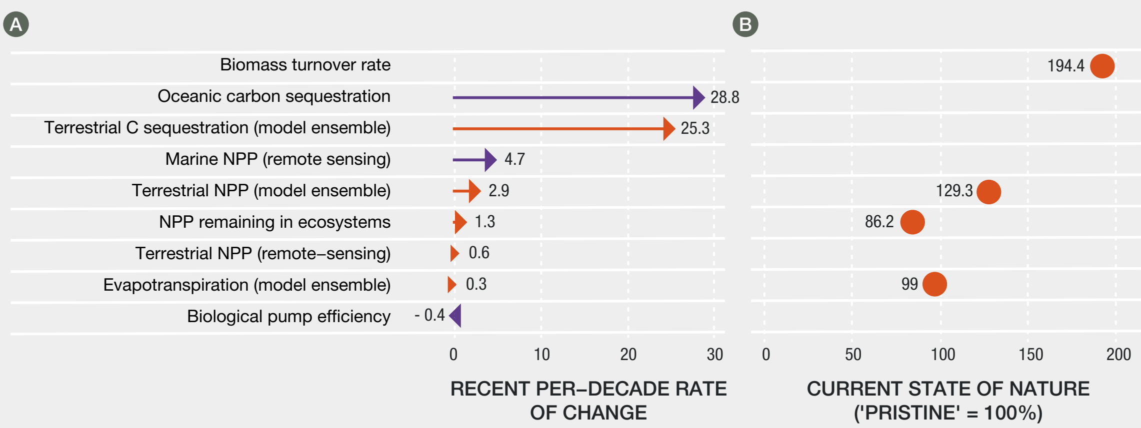

Figure 2 2 11 **Global indicators of rates of ecosystem function.**

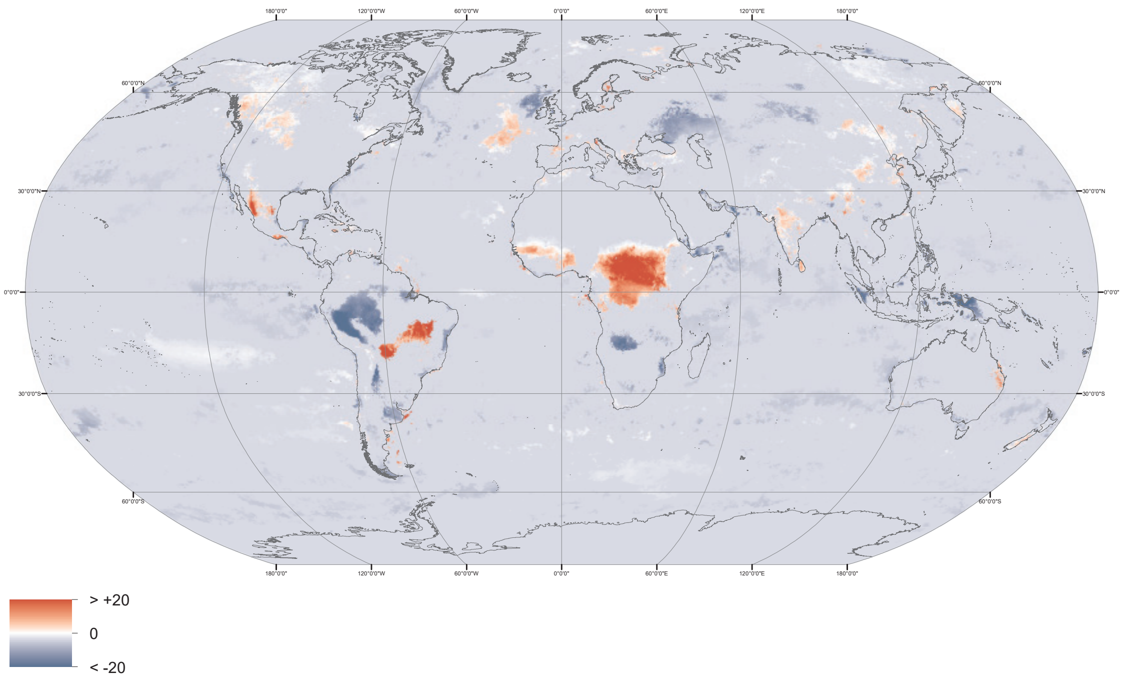
Marine indicators are in purple, terrestrial in orange. A Trends, shown as the average per-decade rate of change since 1970 (or since the earliest post-1970 year for which data are available), ordered by rate of change; seven of the 8 global indicators suggest rates have been increasing (right-pointing arrows). B Estimated current status relative to a pristine or at least largely pre-industrial baseline. Some indicators provide only either rate or status so appear in only one panel. See Supplementary Material S 2.2.3 for detailed information on each indicator and its trend.



Global Net Primary ProductivityTrend 2003 - 2015 (gC/m2/year2)

Figure 2 2 12 **Spatial variation in the trend in terrestrial and marine NPP from 2003-2015, estimated from remote sensing data (terrestrial: Zhao & Running, 2010; marine: Behrenfeld & Falkowski, 1997).**

Note that the spatial pattern has itself changed over time, so may be different in other time windows.

increasing human appropriation of NPP and increasing NPP caused by land management and (increasingly in recent decades) CO_2 fertilization (Krausmann *et al.*, 2013). However, the biotic consequences could be much greater than such a small net change might suggest: agriculture has increasingly channeled terrestrial NPP through a relatively small set of species, reducing the diversity of forms in which that NPP is available to the species in ecosystems.

Knowledge gaps: Ecological communities carry out many more ecosystem functions vital for ecosystem health and the delivery of NCP, such as pollination, decomposition, fruit and seed dispersal, pest control and fertilization of the soil (Díaz *et al.*, 2018; see chapter 2.3); however, available indicators mostly report on either the status of the species responsible or the NCP, rather than on the ecosystem functions and processes linking the two. This partly reflects the difficulties of scaling from local sites, where ecosystem function can be measured, to the globe. More global indicators are needed of rates of ecosystem processes that directly underpin particular NCP or that indirectly underpin ecosystem health.

2.2.5.2.3 Community composition

(N.B. Italics denote indicators plotted in **Figure 2.2.13**)

Local communities are not on average showing rapid changes in species richness, but their biotic integrity is being eroded rapidly by changes in which species are present and abundant (**Figure 2.2.13**, blue background). Local assemblages are also becoming more similar to each other, a pattern known as biotic homogenization. At regional scales, the numbers of species – especially non-native species – have tended to increase over recent decades (**Figure 2.2.13**, orange background).

a. Composition of local communities

The average balance between gains and losses of species in local assemblages worldwide remains unclear (Cardinale *et al.*, 2018), largely because rates of gain (of alien, disturbance-tolerant or other human-adapted species, or of climate migrants) and of loss (though local extinction) are very context-dependent (e.g., Thomas, 2013). The *BioTime species-richness* indicator, estimated as the average trend from a compilation of time-series data from local terrestrial, freshwater and marine assemblages around the world (Dornelas *et al.*, 2014), shows a slight but not statistically significant increase on average with very wide variation from site to site (Dornelas *et al.*, 2014). A compilation of coastal marine assemblages tended to gain species over time, but sites facing local human impacts tended to lose species, especially rare species (Elahi *et al.*, 2015); and a set of local plant communities showed an average decrease in species richness in the tropics but an increase in north temperate regions (Vellend *et al.*, 2013) – assemblages facing disturbance tend to lose species whereas those recovering after disturbance tend to show gains (Gonzalez *et al.*, 2016). Geographic biases in such collations mean they may not accurately reflect the widespread increase in drivers over recent decades (Elahi *et al.*, 2015; Gonzalez *et al.*, 2016). The *PREDICTS species-richness* indicator (Hill *et al.*, 2018), which tries to overcome such geographic biases using a statistical model, shows a slight decrease over time; but the statistical model does not incorporate effects of alien species (Newbold *et al.*, 2015).

Two indicators – *Biodiversity Intactness Index* (BII; De Palma *et al.*, 2018; Hill *et al.*, 2018) and *Mean Species Abundance* (Schipper *et al.*, 2016) – agree that biotic integrity has declined on average to well below its proposed safe limit in the Planetary Boundaries scheme (Steffen *et al.*, 2015b). That framework suggests that large regions whose biotic integrity – i.e., the fraction of originally-present biodiversity that remains – falls below 90% risk large-scale failure of ecosystem resilience that would cause critical reductions in the flows of nature's contributions to people (Steffen *et al.*, 2015b) though there is a great deal of uncertainty about precisely where any boundary should be placed (Mace *et al.*, 2014; Steffen *et al.*, 2015b). A global model (Hill *et al.*, 2018) estimates the *Biodiversity Intactness Index* (BII) to average only 79% across terrestrial ecosystems **(Figure 2.2.14)**, with most biomes below 90%; a model focused on tropical and subtropical forest biomes (De Palma *et al.*, 2018) estimates an even lower BII and more negative trend, as does the global model of *Mean Species Abundance* (Schipper *et al.*, 2016). For both BII indicators and Mean Species Abundance, hotspots of rare and endemic species

Figure 2 2 13 **Global indicators of community composition at the local scale (green background) and the regional scale (orange background).**

Orange symbols are terrestrial indicators, grey symbols are indicators that combine terrestrial, freshwater and marine data. Solid symbols represent overall values for indicators, whereas semi-transparent points represent values for subsets (e.g., for a particular biome or functional group) of the overall indicator. A Trends, shown as the average per-decade rate of change since 1970 (or since the earliest post-1970 year for which data are available), ordered by rate of change. B Estimated current status relative to a pristine or at largely pre-industrial baseline. Some indicators provide only either rate or status so appear in only one panel. Supplementary Materials S 2.2.4 and S 2.2.5 have detailed information and full references for each indicator, including subsets.

have a lower current status and a more negative trend than the global average, whereas indigenous lands have a better current status (though still below the proposed Planetary Boundary) and usually a slower rate of decline **(Figure 2.2.13)**.

b. Compositional dissimilarity between assemblages

Local assemblages are becoming more similar to each other on average, a phenomenon termed biotic homogenization (McKinney & Lockwood, 1999) or the 'anthropogenic blender' (Olden, 2006). When human actions add species to a local assemblage, they are often likely to add the same species to many other assemblages within the region or even around the world; e.g., we plant and farm a relatively small number of species over vast areas of land. The structural, chemical and biotic sameness of these anthromes means that species adapted to them, whether alien or native, can spread widely. Shipping transports ballast water, and its complement of species, from one harbour to another. We move the same pets, pests, pathogens and ornamental species around the world. All of these additions are likely to make the assemblages more similar. At the same time, the species lost from local assemblages because of human actions often differ from place to place, in which case their loss also makes assemblages more similar. A global synthesis reported significant homogenization across nearly all taxonomic groups at nearly all scales (Baiser *et al.*, 2012); further support comes from regional syntheses (e.g., Rahel, 2000; Solar *et al.*, 2015; Winter *et al.*, 2009) and the most detailed field studies (e.g., Gossner *et al.*, 2016).

c. Composition of regional assemblages

Numbers of species in assemblages at larger spatial scales – such as countries or 0.25° grid cells – have tended to increase over recent decades (**Figure 2.2.13**, orange background), partly driven by rapid increases in numbers of non-native species (McGill *et al.*, 2015; Thomas, 2013). A global analysis of establishment of species in new countries from a wide range of taxonomic groups found the *cumulative number of alien species* is rising by 13% per decade, with 37% of all reported establishment events being since 1970 (Seebens *et al.*, 2017). Across 21 countries with particularly good recording of *introduced invasive alien species* (i.e., aliens that cause ecological or economic problems), numbers per country have increased by an average of 70% since 1970 (Pagad *et al.*, 2015). Among the most widespread invaders are the black rat (*Rattus rattus*, 23% of the world's countries), water hyacinth (*Eichhornia crassipes*, 30%), Eastern mosquitofish (*Gambusia holbrooki*, 30%), purple nutsedge (*Cyperus rotundus*, 37%), and cottony cushion scale insects (*Icerya purchasi*, 42%) (Turbelin *et al.*, 2017). Many crop pests and pathogens, especially fungal pathogens, have become widespread, tracking the regional expansion of their host crops (Bebber *et al.*, 2014).

Over 13,000 plant species of plant have become established in countries outside their native range (van Kleunen *et al.*, 2015). Numbers of plant species have increased by an average of 20%–25% across continental regions in Europe and the USA because establishment of aliens has exceeded losses of natives at this scale (Vellend

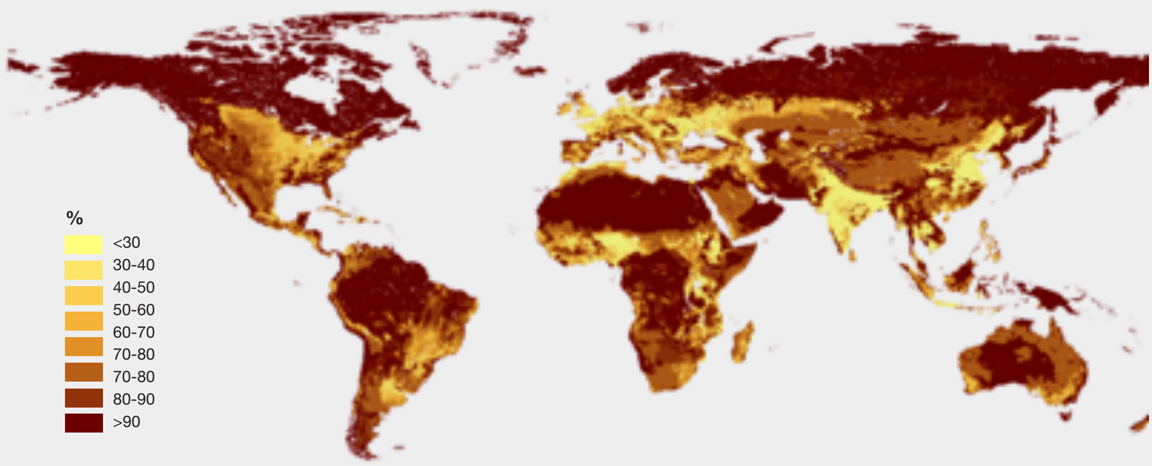


Figure 2 2 14 **Global map of estimated terrestrial Biodiversity Intactness Index in 2015 (Hill *et al.*, 2018).**

Darker colours indicate more intact ecological community composition.

et al., 2017); regional plant species richness is estimated to have increased by 5% or more across nearly half of the world's land surface and decreased similarly across only 14% (Ellis *et al.*, 2012). Alien species make up a smaller fraction of the flora in tropical countries than in temperate ones, but too little is known about national extinctions in the tropics to be sure that the net change there has been an increase (Vellend *et al.*, 2017). *Species richness per grid cell* (Kim *et al.*, 2018)*,* modelled across plants, birds, mammals, amphibians and reptiles, has fallen slightly since 1970 because of changes in land use and climate. However, this model omits species introductions (Kim *et al.*, 2018), which would make the trend more positive; and, even without introductions, the indicator is still higher than in 1900 for most groups. A conceptually similar model (Kim *et al.*, 2018; Pereira & Daily, 2006) estimates that *bird species per grid cell* has risen slightly since 1970, but that *forest-specialist bird species per grid cell* has fallen, and more steeply. A mechanistic general ecosystem model (Harfoot *et al.*, 2014) suggests that average *functional intactness* (i.e., the extent to which a region's species still occupy the functional trait space of its native species) is falling because of harvesting of primary productivity and climate change (Kim *et al.*, 2018).

Island assemblages are likely to be an exception to the general trend towards increased species numbers. They can be devastated by invasive alien species (e.g., Bergstrom *et al.*, 2009; O'Dowd *et al.*, 2003; Reaser *et al.*, 2007), in part because native species may have evolved in the absence of strong competition, predation or pathogens (Courchamp *et al.*, 2003). Introduced mammalian predators have removed many native bird species from oceanic islands worldwide (Blackburn *et al.*, 2004), reducing diversity at the island scale. Introduced plant species, by contrast, have roughly doubled the numbers of plant species on a set of well-documented oceanic islands (Carvallo & Castro, 2017; Sax & Gaines, 2008). Even though they may increase regional diversity, though, invasive alien plants usually reduce numbers of species in local assemblages on islands (Pyšek *et al.*, 2012) and can have profound ecosystem impacts (e.g., Dulloo *et al.*, 2002; Pyšek *et al.*, 2012).

Some invasive alien species on mainlands can also drive reductions in regional-scale diversity, by causing native species to decline. *Batrachochytrium dendrobatidis*, an infectious fungal pathogen that has infected over 700 amphibian species worldwide, has caused a number of extinctions, and is recognized as a threat to nearly 400 species (Bellard *et al.*, 2016; Lips, 2016; Olson *et al.*, 2013).

Even where regional species richness has increased, the increase may be temporary because an 'extinction debt' has not yet been repaid (Jackson & Sax, 2010). Biotic responses to drivers of change are often not immediate, meaning recent intensification of any driver can produce 'dead species walking', certain to disappear from the region unless the drivers of their decline are reversed (Kuussaari *et al.*, 2009). Extinction debts are discussed in more detail in Section 2.2.5.2.4a below.

Knowledge gaps: Available indicators all relate to the taxonomic or functional composition rather than the interactions among organisms and taxa. Indicators overwhelmingly relate to terrestrial free-living animal and plant species: freshwater and marine assemblages are greatly underrepresented, and microbial and parasite assemblages entirely so. As yet there are no global indicators of biotic homogenization.

2.2.5.2.4 Species populations

(N.B. Italics denote indicators plotted in **Figure 2.2.16**)

a. Extinctions, extinction risk and extinction debt

The most direct evidence on global extinctions and extinction risk comes from the detailed assessments of species' conservation status undertaken by the IUCN (International Union for the Conservation of Nature). IUCN has assessed the global conservation status of 93,579 species, mostly vertebrates, of which 872 (0.9%) have gone extinct since 1500 (IUCN, 2018). Under-recording and time lags in recognizing extinction events make this a certain underestimate of the true number (Alroy, 2015; Dunn, 2005; Pimm *et al.*, 2006; Scheffers *et al.*, 2012; Stork, 2010), especially in less well studied groups (e.g., only 62 species of insect are listed as extinct; but fewer than 1% of insects have been assessed; IUCN, 2018) and habitats (e.g., only 20 marine extinctions have been recorded; Webb & Mindel, 2015). In the best-recorded groups, mammals and birds, around 1.4% of species are known to have gone globally extinct since 1500, most of them since 1875 (IUCN, 2018).

The global rate of species extinction is already at least tens to hundreds of times higher than the average rate over the past 10 million years, and is accelerating (Barnosky *et al.*, 2011; Ceballos *et al.*, 2015; Pimm *et al.*, 2014); the difficulties of estimating and comparing current and past extinction rates (Barnosky *et al.*, 2011; Ceballos *et al.*, 2015; Pimm *et al.*, 2014) preclude greater precision. The extinction rate therefore already exceeds its proposed safe limit (set at ten times the average rate (Steffen *et al.*, 2015b)) in the Planetary Boundaries framework, though the suggestion that elevated rates may eventually trigger sharp and irreversible changes in the Earth system (Steffen *et al.*, 2015b) has been criticized (Brook *et al.*, 2013; Mace *et al.*, 2014). Extinction rates would be still higher but for successful conservation (Butchart *et al.*, 2006, chapter 3).

Extrapolating from detailed assessments of species across a growing and diverse set of well-studied taxonomic groups, it is probable that at least a million animal and plant species – more than one in eight – already face global extinction. The proportion of species currently threatened with global extinction (i.e., listed in the IUCN Red List as Vulnerable, Endangered or Critically Endangered) averages around 25% across a wide range of animal and plant taxonomic groups (range = 7.4%–63.2%, median = 22.1%; **Table 2.2.1**). The current prevalence of extinction risk appears to be similar between terrestrial and marine realms, from the few marine groups in **Table 2.2.1** and from models of how threat prevalence scales with the comprehensiveness of Red List assessments (Webb & Mindel, 2015). No global estimate of extinction risk prevalence is yet available for any of the hyperdiverse insect orders. However, a cautious estimate of 10% is reasonable, based on the Red Lists for Europe (the region with the best data), which report that 9.2% of bee species (Nieto *et al.*, 2014), 8.6% of butterflies (Van Swaay *et al.*, 2010) and 17.9% of saproxylic beetles (Cálix *et al.*, 2018) are threatened with regional extinction. For context, in vertebrates, Europe's levels of regional extinction risk are lower than the overall levels of global extinction risk (EU, 2018). If insects make up three quarters of animal and plant species (Chapman, 2009) and only 10% of them are threatened as opposed to 25% of species in other groups, then overall nearly 14% of animal and plant species are threatened with extinction, i.e., more than a million using the estimated total number of 8.1 million (Mora *et al.*, 2011).

Table 2 2 1 **Proportions of evaluated species.**

The first figure given assumes that Data Deficient species are equally likely as other species to be threatened. The range reported shows the proportion if Data Deficient species are assumed to be not threatened and threatened, respectively. Basis of estimate: all species = comprehensive assessment of whole group; sample = representative sample assessed; some families = all species within some families assessed, but families may not be representative.

Group	Threatened species (%)	Possible range (%)	Basis of estimate	Reference
Vertebrates				
Amphibians	41.49%	32-55%	all species	(IUCN, 2018)
Birds	13.47%	13-14%	all species	(IUCN, 2018)
Bony fishes	7.41%	7-18%	some families	(IUCN, 2018)
Mammals	25.17%	22-36%	some families	(IUCN, 2018)
Marine mammals	38.70%	30-52%	marine species	
Reptiles	18.99%	15-36%	sample	(Böhm *et al.*, 2013)
Sharks & rays	31.18%	18-60%	all species	(IUCN, 2018)
Invertebrates				
Crustaceans	27.49%	17-56%	some families	(IUCN, 2018)
Gastropods	7.52%	6-20%	some families	(IUCN, 2018)
Odonata	15.38%	10-45%	sample	(Clausnitzer *et al.*, 2009)
Reef-forming corals	32.91%	27-44%	all species	(IUCN, 2018)
Plants				
Cycads	63.16%	63-64%	all species	(IUCN, 2018)
Dicots	36.14%	32-44%	some families	(IUCN, 2018)
Legumes	11.30%	11-18%	sample	(Brummitt *et al.*, 2015)
Gymnosperms	40.55%	40-42%	sample	(Brummitt *et al.*, 2015)
Monocots	17.51%	15-27%	sample	(Brummitt *et al.*, 2015)
Pteridophytes	16.01%	15.9-16.4%	sample	(Brummitt *et al.*, 2015)

Numbers of threatened vertebrate species show wide geographic variation both on land and at sea **(Figure 2.2.15)**, reflecting where large numbers of narrowly-distributed species (see Section 2.2.3.4.2) face often intense, often multiple anthropogenic drivers (Hoffmann *et al.*, 2010).

The *Red List Index* (RLI) (Butchart *et al.*, 2007, 2010) tracks overall trends in survival probability (the inverse of extinction risk) of species in taxonomic groups whose IUCN Red List status has been assessed multiple times. Overall, the RLI is now only 75% of the value it would have without human impacts **(Figure 2.2.16)**, though this varies among taxonomic groups (e.g., birds have an RLI around 90% but for cycads RLI is below 60%: chapter 3). Regions showing the greatest deterioration in RLI include much of Southeast Asia and Central America (Hoffmann *et al.*, 2010). RLI values calculated for sets of species that directly deliver some NCP – *internationally-traded species*, *pollinating vertebrate species*, *species used in food and medicine*, and *wild relatives* of farmed and domesticated mammals and birds – are higher than the overall value and are declining more slowly, but they are all declining. Species' progress towards extinction appears to be increasingly rapid: half of the decline in the overall Red List Index has taken place in the last 40 years.

Few insects have global IUCN assessments, but regional and national assessments of insect pollinators often indicate high levels of threat, often more than 40% of species threatened at a national scale, particularly for bees and butterflies (IPBES, 2016). Recent European scale assessments indicate that 9.2% of bees (Nieto *et al.*, 2014) and 8.6% of butterflies (Van Swaay *et al.*, 2010) are threatened. Bee species that pollinate crops are generally common with a low prevalence of extinction risk (IPBES, 2016).

Whereas IUCN's detailed Red List assessments of species form the basis for 'bottom-up' estimates of numbers of threatened species, an alternative 'top-down' approach can be used to estimate the 'extinction debt' – i.e., how many species are expected to eventually go extinct because of habitat deterioration that has already taken place (Kuussaari *et al.*, 2009). The earliest estimates of extinction debt (Diamond, 1972) were based directly on one of the strongest patterns in biodiversity, the species-area relationship: the number of species in a region increases

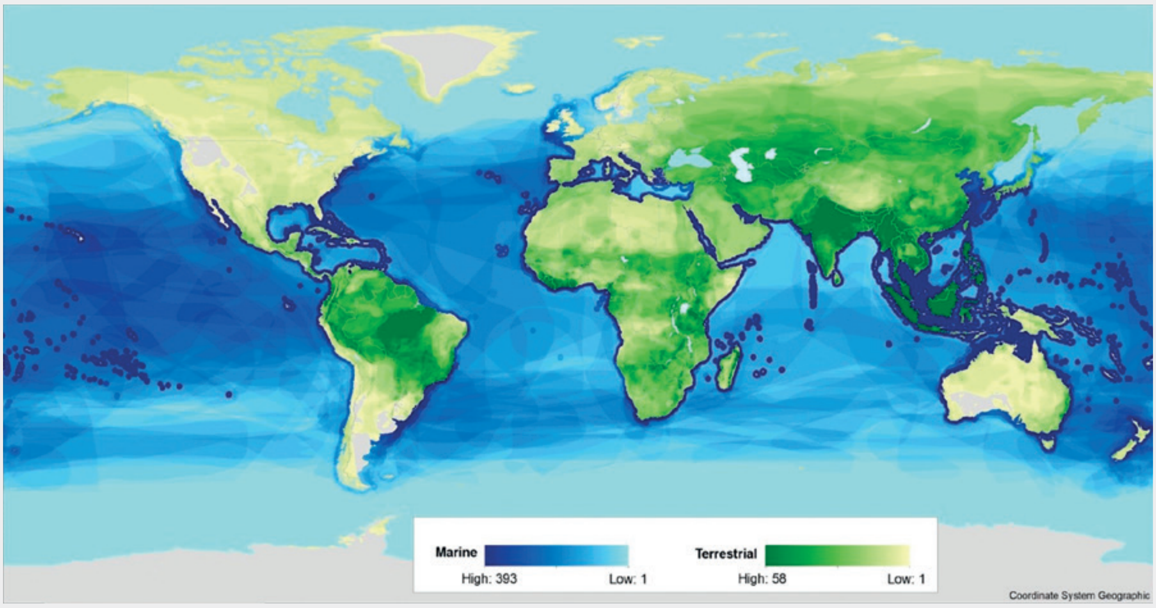

Figure 2 2 15 **Numbers of threatened (i.e., vulnerable, endangered or critically endangered) species per 10km grid cell, pooled from comprehensive geographic distribution and extinction-risk assessments of multiple taxonomic groups.**

Green = terrestrial (amphibians, birds, chameleons, crocodiles/alligators and mammals); blue = marine (angelfish, birds, blennies, bonefish/tarpons, butterflyfish, marine turtles, sharks/rays, Conus cone shells, corals, damselfish, groupers, hagfish, lobsters, mammals, mangroves/seabreams/porgies, pufferfish, sea cucumbers, seagrasses, sea snakes, sturgeonfish/tangs/unicornfish, tunas/billfishes and wrasse; grey = no data. Darker colours indicate higher numbers of threatened species. Note that only a small minority of taxonomic groups have so far been assessed, with a bias towards vertebrates especially on land. Methods as in Hoffmann *et al.* (2010). Figure produced by UNEP-WCMC.

predictably with its area (often as a power law), because larger regions both have greater habitat diversity and can support larger numbers of viable populations (Lewis, 2006; Rosenzweig, 1995). Habitat loss effectively makes the region smaller. Though this loss of area may not wipe any species out immediately, it means that the region now has more species than expected: this excess of species is the extinction debt, and all the region's species will have elevated probabilities of extinction until the diversity falls back to the level expected from the species-area relationship. Such approaches do not identify precisely which species in the region will go extinct; they may not meet IUCN's criteria for being listed as threatened, for example. Nor do these approaches specify how long the extinctions will take: although the first extinctions may arrive quickly, the last ones may take centuries, especially in large regions and/or when species have long generation times (Halley *et al.*, 2016; Kuussaari *et al.*, 2009; Vellend *et al.*, 2006). The estimates of extinction debt used here come from models with more sophisticated species-area relationships that consider species' habitat preferences and geographic distributions, and habitat condition as well as extent (Hoskins *et al.*, 2018; Kim *et al.*, 2018; Pereira & Daily, 2006), meaning many of the criticisms of earlier approaches (He & Hubbell, 2011; Lewis, 2006; Pereira *et al.*, 2012) no longer apply. Furthermore, they use entirely different data and methods from the Red List assessments, so provide a completely independent line of evidence.

The most comprehensive global estimate available (Hoskins *et al.*, 2018) suggests that the terrestrial extinction debt currently stands at hundreds of thousands of animal and plant species. The loss of terrestrial habitat integrity estimated by the *Biodiversity Habitat Index* (Hoskins *et al.*, 2018), when coupled with the species-area relationship, suggests that only 92.1% of terrestrial vertebrate species, 91.6% of terrestrial invertebrates and 90.7% of terrestrial plants have sufficient habitat to persist. The numbers of plant and especially animal species remain very uncertain (Caley *et al.*, 2014; Scheffers *et al.*, 2012), but a recent non-extreme estimate of 8.1 million of which 2.2 million are marine (Mora *et al.*, 2011), these proportions suggest that around half a million terrestrial animal and plant species are 'dead species walking', committed to extinction unless their habitats improve in time to prevent it. This total includes over 3000 vertebrates and over 40,000 plants. Even this estimate may be conservative, as undocumented diversity of arthropods, parasites and soil microfauna could mean there are 2–25 times more animal species than assumed here (Larsen *et al.*, 2017), and fungi are not included (Scheffers *et al.*, 2012). Using a related approach, the countryside species-area relationship (cSAR), to estimate the *global bird richness* that can persist suggests that 97.6% of the world's bird species, but only 94.9% of forest-specialist birds, will avoid extinction resulting from past habitat loss.

These two very different lines of evidence both point to a further sharp acceleration in the global rate of species extinction, already at least tens to hundreds of times higher than the average rate over the past 10 million years and is accelerating. The numbers of threatened species that will go extinct if the drivers that threaten them continue, and the numbers of 'dead species walking' that will die out even without any further habitat deterioration or loss, dwarf the numbers of species already driven extinct by human actions (Johnson *et al.*, 2017; Wearn *et al.*, 2012). Rapid large-scale restoration of habitats can pardon the 'dead species walking', provided it takes place in time (Kuussaari *et al.*, 2009); and even much less widespread restoration can greatly delay extinctions if targeted optimally (e.g., Newmark *et al.*, 2017).

b. Geographic distribution and population size

Nearly all global indicators of geographic distribution (**Figure 2.2.16**, blue background) and population size (**Figure 2.2.16**, cream background) show rapid decline, reflecting widespread reductions in animal populations on land (Ceballos *et al.*, 2017; Dirzo *et al.*, 2014) and sea (McCauley *et al.*, 2015), though most global indicators focus on vertebrates. Several indicators are calculated in a way that makes them particularly sensitive to trends in rare species (Buckland *et al.*, 2011), and these all show rapid declines: *The Living Planet Index* (LPI) for vertebrate populations (McRae *et al.*, 2017); the *Wild Bird Index* for habitat-specialist birds; and the *extent of suitable habitat* for terrestrial mammals (Kim *et al.*, 2018; Visconti *et al.*, 2016). The *Species Habitat Index*, which changes in direct proportion to average species range size (Map of life, 2018), has shown more modest recent declines in terrestrial vertebrates. *Mammalian range size* has been reduced to an average of 83% of species' inferred original ranges, but *megafaunal range size* – species larger than 44.5kg – is now only 28% of the natural baseline (Faurby & Svenning, 2015), with large mammal ranges having declined particularly rapidly in south and southeast Asia (Ceballos *et al.*, 2017). *Predatory fish biomass* (which includes the main target species for fisheries (Christensen *et al.*, 2014)) has been falling by -14% per decade, and the proportion of *fish stocks within biologically sustainable levels* by 6% per decade (to less than 70%) (FAO, 2016d). The *biomass of prey fish* **(Figure 2.2.16)** has been rising by 10% per decade, the only indicator to show an increase, probably because fishing has removed predatory fish (Christensen *et al.*, 2014). Such indirect responses to anthropogenic drivers are ubiquitous and can have profound effects on many aspects of ecosystems (Dirzo *et al.*, 2014; McCauley *et al.*, 2015).

Invertebrate trends have not so far been synthesized globally, because of a dearth of tropical data. An LPI-like analysis of mainly European and North American data reported a decline of -11% per decade (Dirzo *et al.*, 2014).

The same regions have seen declines in geographic distribution and occurrence of many wild bees and butterflies (IPBES, 2016); and, of species with enough information to make an assessment, 37% of bees and 31% of butterflies are declining in Europe (IPBES, 2016; Nieto *et al.*, 2014; Van Swaay *et al.*, 2010). Available time-series data show that local declines of insects can be rapid even in the absence of large-scale land-use change (e.g., 76% decline over 27 years in biomass of flying insects in sites in 63 protected areas in Germany (Hallmann *et al.*, 2017)); it is not known how widespread such rapid declines are.

Although many species are declining, farmed species, domesticates, and species that are well adapted to anthromes have all increased in abundance. A hectare of wheat will often have more than 500,000 established plants – and wheat is planted on around 220 million ha each year (Rudel *et al.*, 2009); the number of managed western honey bee hives is increasing globally (IPBES, 2016); and livestock now accounts for over 90% of megafaunal biomass on land (Barnosky, 2008).

Knowledge gaps: There are shortages of detailed knowledge of conservation status and population trends in insect, fungal and microbial species. Tropical populations are extremely underrepresented in trend data.

Figure 2 2 16 **Global indicators of species population, reflecting persistence of species (orange background), geographic range size (green background) or population size (cream background).**

Terrestrial indicators are shown in orange, marine in purple, freshwater in yellow, and multi-realm indicators in grey. Solid symbols represent overall values for indicators, whereas semi-transparent points represent values for subsets (e.g., within hotspots of endemic species) of the overall indicator. A Trends, shown as the average per-decade rate of change since 1970 (or since the earliest post-1970 year for which data are available), ordered by rate of change. B Estimated current status relative to a pristine or at largely pre-industrial baseline. Some indicators provide only either rate or status so appear in only one panel. Supplementary Materials S 2.2.6 and S 2.2.7 have detailed information and full references for each indicator, including subsets.

2.2.5.2.5 Organismal traits

(N.B. Italics denote indicators plotted in **Figure 2.2.18**)

Human activities have driven and continue to drive widespread changes in distributions of organismal traits within populations **(Figure 2.2.17)** and in local, regional, and global assemblages (**Figure 2.2.18**, **Figure 2.2.19**). Traits not only mediate how populations and communities respond to changing environments (e.g., Diaz *et al.*, 2013; Hevia *et al.*, 2017; Jennings & Kaiser, 1998; Mouillot *et al.*, 2013; Suding *et al.*, 2008) but also strongly influence species' likelihoods of being exploited (Jerozolimski & Peres, 2003), persecuted (Inskip & Zimmermann, 2009), domesticated (Larson & Fuller, 2014), introduced (Theoharides & Dukes, 2007) or otherwise impacted by people. Rapid evolution **(Box 2.5)** contributes to the changes, alongside phenotypic plasticity (in which the environment shapes how an organism's phenotype develops) and ecological processes. The combined effects typically shift both average trait values (e.g., toward smaller body size) and the amount of trait variation (e.g., reducing the range of trait values). The changes in trait distributions matter because they can have consequences, sometimes major, for ecosystem functioning, NCP, and whether ecosystems will be resilient in the face of ongoing environmental change (Diaz *et al.*, 2013; Laliberté *et al.*, 2010; Lavorel & Garnier, 2002).

Few quantitative indicators are available that show how distributions of organismal traits have changed globally, but there is an extensive literature showing how each of the main direct drivers affects both trait distributions among and within species. This section highlights some recent examples, while **Box 2.5** focuses on within-population changes, especially heritable genetic changes – evolution.

Land-use change causes the assembly of new ecological communities, often with very different trait distributions from the community present previously. Forest removal obviously greatly changes distributions of plant traits, for instance, but also reshapes trait distributions in tropical bird assemblages: long-lived, large, non-migratory, forest-specialist frugivores and insectivores become less abundant and less widespread (Newbold *et al.*, 2013). Increasing land use led to European plant communities being dominated by shorter species with more acquisitive leaf syndromes and accelerated flowering phenology (Garnier *et al.*, 2007). Bee species' responses to changing land use in Europe depend on flight season duration, foraging range and, to a lesser extent, niche breadth, reproductive strategy and phenology (De Palma *et al.*, 2015). A global meta-analysis found that intensification of land use was associated with greater reduction of functional diversity in mammal and bird assemblages than expected from the number of species lost (Flynn *et al.*, 2009).

Direct exploitation often targets older, larger and more accessible individuals, so shifts trait distributions in the opposite direction. For example, large, diurnal, terrestrial mammals have been particularly likely to face hunting pressure (Johnson, 2002), and species of tuna and their relatives that grow and reproduce more slowly have declined more than other species in the face of fishing pressure (Juan-Jordá *et al.*, 2015). Such phenotype-dependent mortality holds both among populations within species (Darimont *et al.*, 2009), so larger-bodied species are lost from communities, larger-bodied populations are lost from species, and many populations rapidly evolve smaller body size and earlier maturation **(Box 2.5)**.

Climate change tends to shift trait distributions away from low reproductive rates, poor dispersal abilities and ecological specialism (as species with these traits are less able to persist when climate change: (Pacifici *et al.*, 2015)) and towards more flexible, environmentally responsive, phenotypes (e.g., plants: Willis *et al.*, 2008; birds: Both *et al.*, 2006; Nussey *et al.*, 2005) and earlier spring phenology in seasonal environments (e.g., earlier bud break for plants, earlier hatching and emergence for insects, and earlier breeding for birds and mammals; Parmesan & Yohe, 2003; Wolkovich *et al.*, 2012). Global changes in phenology have been dramatic: between 1981 and 2012, the phenology of vegetation (timing of leaf onset and offset) has changed by more than 2 standard deviations across 54% of the global land surface (Buitenwerf *et al.*, 2015), and growing seasons have lengthened (Linderholm, 2006), in the Arctic by more than 3 days per decade (Xu *et al.*, 2013). This information is policy relevant because it can influence decisions about assisted migration (moving species to locations where they will be better suited for the new climate; McLachlan *et al.*, 2007).

Pollution also reshapes trait distributions, in ways that differ among pollutants and species. Effects of different classes of insecticide on aquatic invertebrates, for example, are mediated by the body size, respiration type and degree of sclerotization of species, populations and individuals (Rico & Van den Brink, 2015).

Invasive alien species can increase trait and functional diversity having different trait values from natives (Hejda & de Bello, 2013; Ordonez *et al.*, 2010; Van Kleunen *et al.*, 2010), but their trait-mediated effects on native species can also change overall trait distributions. A global meta-analysis of 198 studies found that invasive plants tend to reduce diversity and abundance of herbivorous and carnivorous animals but not detritivores or omnivores (Schirmel *et al.*, 2016), thereby changing the trophic diversity of assemblages.

Indirect effects of drivers – knock-on effects – can also select against particular organismal traits and therefore affect trait distributions. Most obviously, species that depend on just one or a narrow set of other species, whether as a host, food, pollinator, or disperser, will often be vulnerable if that species declines (Dunn *et al.*, 2009).

Species' extinction risk, which integrates across all direct and indirect drivers at the global level, is strongly related to organismal traits in a wide range of taxonomic groups. The traits that are most likely to be lost from assemblages through extinction differ somewhat among groups, but commonly include habitat and dietary specialism, slow reproductive rate, and large body size (Bland, 2017; Böhm *et al.*, 2016; Cardillo *et al.*, 2005; Cooper *et al.*, 2008; Davidson *et al.*, 2009; Dulvy *et al.*, 2014; Fritz *et al.*, 2009; Lee & Jetz, 2011; Mankga & Yessoufou, 2017; Owens & Bennett, 2000).

Box 2 5 Rapid evolution.

Evolution is typically assumed to be a very slow process, with many species exhibiting remarkable stability over millions of years. This stability is mostly a function of precise adaptation to relatively stable environments; hence, when environments change rapidly, we might expect rapid evolutionary responses. Human actions mean that many species are facing radical changes in their environments, setting up the conditions for many populations to show rapid trait change. **Figure 2.2.17**, based on an extensive review of over 4000 rates of trait change from over 350 studies, reveals that each of the main direct drivers can provoke rapid trait change, as can natural disturbances.

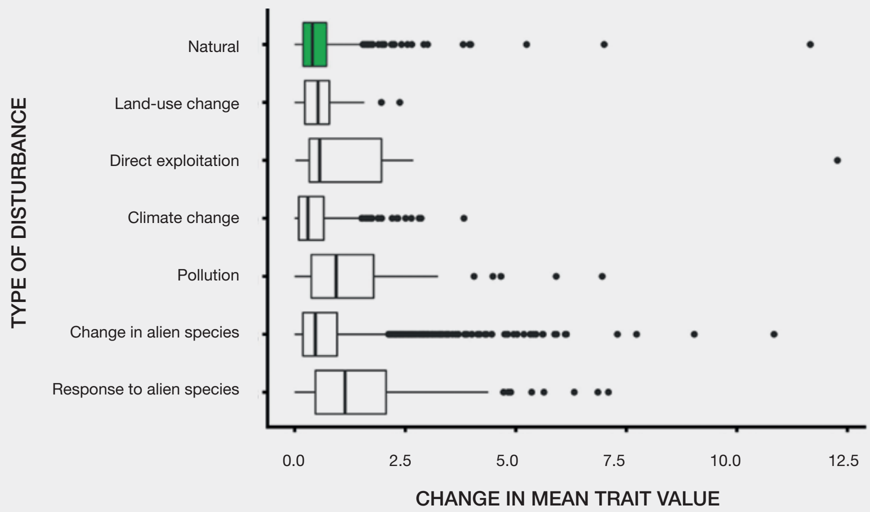

Figure 2 2 17 **Meta-analysis of published estimates of rapid changes in trait means (expressed as the population's change in the mean trait value divided by its standard deviation) within populations that faced natural disturbances or the direct anthropogenic drivers of change.**

Vertical lines indicate medians, and boxes span 25th-75th percentiles. Sample sizes: natural disturbance, 574 effects (49 studies); land-use change, 122 (19); direct exploitation, 18 (7); climate change, 327 (197); pollution 68 (12); change in alien species, 3329 (87); change in native responding to alien species, 223 (10).

Attributing rapid trait changes to evolution (genetic change), plasticity (direct environmental influences on individual development or behaviour), or a combination of both, takes additional focused investigation. Nonetheless, numerous case studies are demonstrating rapid evolution in response to each of the main direct drivers. For example:

- Land-use change caused significant genetic differentiation among plant populations in grassland sites facing different land uses and intensities, in all eight species tested (Völler *et al.*, 2017)
- Direct exploitation is likely to cause evolutionary change whenever the phenotypes it targets are under genetic control. For instance, trophy hunting of bighorn sheep drives the rapid evolution of smaller horn size (Pigeon *et al.*, 2016); while commercial fishing drives the rapid evolution of smaller size and earlier maturity (Sharpe & Hendry, 2009) – although it can be hard to prove a genetic basis underlying the change.
- Climate change is driving rapid evolution in many populations and species (Merilä & Hendry, 2014). For instance, pitcher

plant mosquitoes *(Wyeomyia smithii)* have evolved earlier pupation timing in accordance with earlier spring warming (Bradshaw & Holzapfel, 2002).

- Pollution can rapidly drive evolution of tolerance (Hamilton *et al.*, 2017), with a recent example being killifish *(Fundulus heteroclitus)* adapting to PCBs in estuaries along the eastern coast of North America (Reid *et al.*, 2016).

Cities present novel and in many ways extreme environments and are driving rapid evolution in many species (Alberti *et al.*, 2017; Johnson & Munshi-South, 2017). Two clear recent examples are the evolution of freeze-tolerance of white clover, *Trifolium repens* (Thompson *et al.*, 2016), and the evolution of significantly reduced dispersal another plant species, *Crepis sancta*, within 12 generations in response to urban habitat fragmentation (Cheptou *et al.*, 2017).

Evolutionary change in these traits likely influences the ability of organisms to persist and thrive in altered environments, a phenomenon called "evolutionary rescue" (Carlson *et al.*, 2014). Yet evolution won't always save populations or species – the outcome depends on many factors, including the demographic cost imposed by the disturbance, the strength of selection, and the genetic variation available for evolution. Hence, policy decisions that seek to maintain populations and species can manipulate these factors to maximize population persistence and productivity, and nature's contributions to people. For example, alternative harvesting regimes can drive different evolutionary changes that can have different effects on sustainability and productivity (Dunlop *et al.*, 2018; Jørgensen *et al.*, 2009); tailoring hunting or fishing regulations, such as maximum or minimum allowable sizes, can reduce the evolution of smaller body size and earlier reproduction (Dunlop *et al.*, 2009). As another example, moving individuals with beneficial genotypes between populations can facilitate rapid adaptation to new climate conditions (i.e., assisted gene flow: Aitken & Whitlock, 2013; McLachlan *et al.*, 2007).

Policy decisions that influence rapid evolution can also be used to reduce the impact of harmful species, such as pest or pathogens. For instance, the rapid evolution of antibiotic resistance in many bacterial pathogens, and the rapid evolution of pesticide- and GMO-crop resistance in many crop pests, have been identified as major threats to human wellbeing (Carroll *et al.*, 2014; World Economic Forum, 2018). Hence, evolutionarily-informed policies have been used to slow the evolution of resistance (Carroll *et al.*, 2014; Tabashnik *et al.*, 2008); e.g., "refuges" – areas not planted with GMO crops or not sprayed with insecticides – are routinely used to prevent the evolution of resistance by insect pests to GMO crops or insecticides (Carrière *et al.*, 2010; Tabashnik *et al.*, 2008). Similarly, control of mosquitoes has been severely hampered by their evolution of pesticide-resistance, leading to the development of control strategies that are evolution-resistant (Read *et al.*, 2009) or that also make use of evolution: for instance, 'gene drive' can cause the rapid evolution of phenotypes that have much lower (rather than higher) fitness, and thus may disrupt mosquito reproduction or malarial transmission (Eckhoff *et al.*, 2016).

The following publications contain more details (Kok *et al.*, 2018; PBL, 2012, 2014; van Vuuren *et al.*, 2015; Visconti *et al.*, 2016), and there is discussion about their regional results in each IPBES regional assessment.

The widespread trait-mediated effects of drivers have caused dramatic shifts in organismal trait distributions (means and variances), though few global indicators are yet available **(Figure 2.2.18)**. The *Marine Trophic Index*, which reflects the average trophic level of fish caught within multiple regions, has fallen from around 4.0 to around 3.6 in the last 60 years, because fishing preferentially removes larger, more predatory fish (Pauly *et al.*, 1998): the proportion of global fish biomass that is made up of predatory fish has declined by a factor of around 10 since

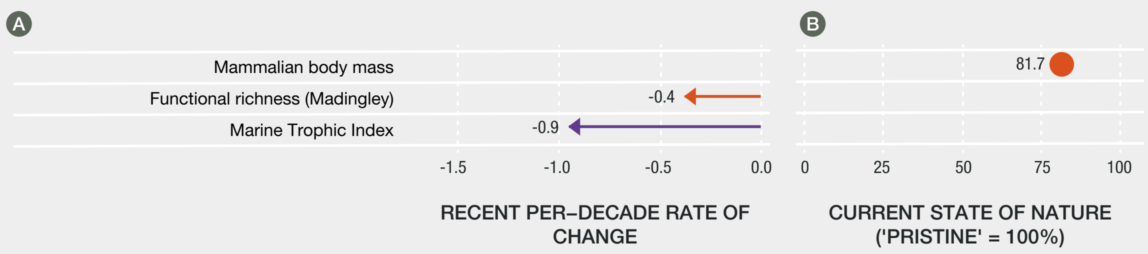

Figure 2 2 18 **Global indicators of species traits.**

Marine indicators are in purple, terrestrial in orange. A Trends, shown as the average per-decade rate of change since 1970 (or since the earliest post-1970 year for which data are available), ordered by rate of change. B Estimated current status relative to a pristine or at least largely pre-industrial baseline. No indicators provide both trend and status. See Supplementary Material S 2.2.9 for detailed information on each indicator.

1880 (Christensen *et al.*, 2014). The declining size of harvested individuals can reduce fishery productivity (Dunlop *et al.*, 2015). On land, the median *mammalian body mass* of species within 1° grid cells has fallen by 18% (Santini *et al.*, 2017), while a general ecosystem model (Harfoot *et al.*, 2014) estimates that *functional richness* within 0.5° grid cells is falling worldwide.

Changes in trait means can have important consequences for population dynamics, community structure, ecosystem functioning, and, more generally, nature's contributions to people. For example, the widespread declines of large species are already profound affecting many ecosystem functions at sea and on land (Dirzo *et al.*, 2014; McCauley *et al.*, 2015; Ripple *et al.*, 2014). Extinct terrestrial megafauna maintained a degree of openness in forest structure, giving landscapes high habitat diversity; their loss has led to more forest canopy closure and has also changed fire regimes (Johnson, 2009), greatly reduced long-distance dispersal of many fruits (Pires *et al.*, 2018) and dispersal of productivity-limiting nutrients (Doughty *et al.*, 2013), as well as affecting many other ecosystem processes (Ripple *et al.*, 2015). Likewise, the historical and ongoing loss of large species from oceans has reduced connectivity among ecosystems and reduced their temporal stability (McCauley *et al.*, 2015).

Changes in trait diversity are important as well as changes in mean values, because the assemblage-level diversity in how populations respond to drivers of change underpins ecosystem stability and resilience under drivers of change (Diaz & Cabido, 2001; Elmqvist *et al.*, 2003). For instance, both among- and within-population diversity in adaptive life history traits in salmon tend to stabilize temporal variation in overall abundance and hence harvest (Schindler *et al.*, 2013). Similarly, different plant genotypes have different effects on arthropod communities, soil microbial communities, decomposition rates, nutrient cycling, and nitrogen mineralization (Bailey *et al.*, 2009).

Knowledge gaps: Few global indicators synthesize changes over time in organismal traits across large numbers of species, and none that does so for trait-based estimates of functional diversity, despite its ecological importance.

2.2.5.2.6 Genetic composition

Within-population genetic diversity has been lost at the rate of about 1% per decade since the mid-19th century, according to the only global meta-analysis (76 studies of 69 species; Leigh *et al.*, 2018). Island populations in

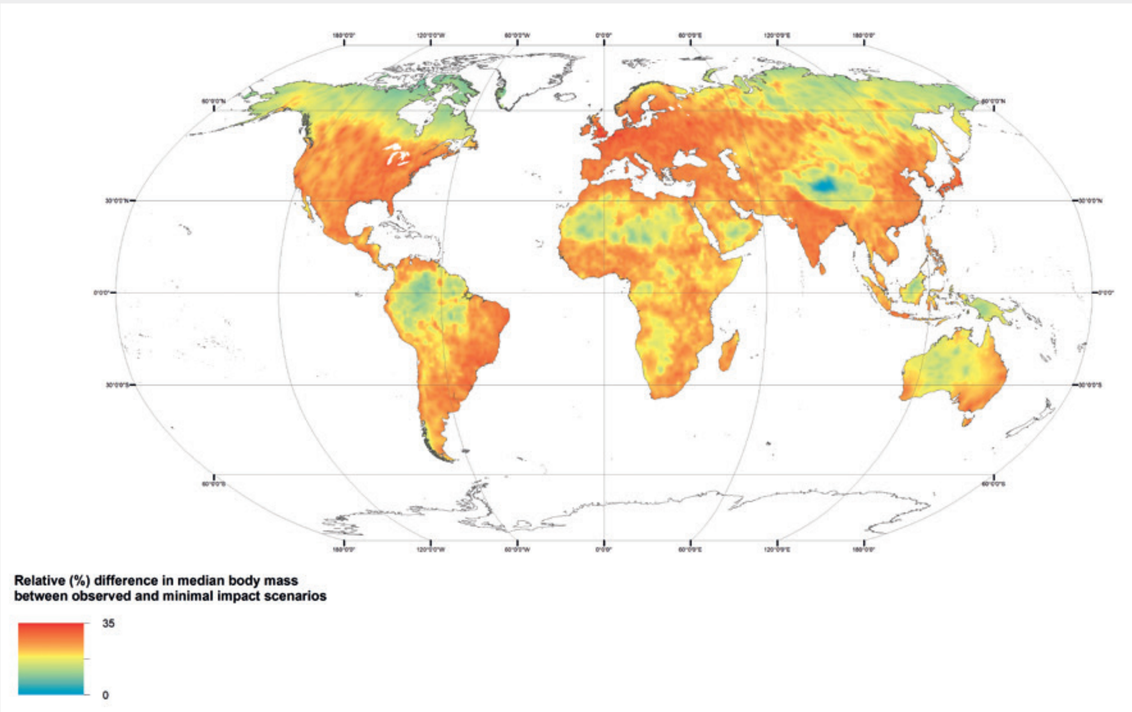

Figure 2.2.19 **Geographic variation in the percentage reduction in median mammalian body mass as a result of species range loss caused by human impacts.**

Data from Santini *et al.* (2017).

the survey tended to have lost more genetic diversity than mainland populations: those from Mauritius and the Seychelles have lost an average of 49% of their genetic diversity (Leigh *et al.*, 2018). Support for a general human-caused decline comes from a map showing that within-species genetic diversity of amphibians and mammals tends to be lower in areas with greater human influences, especially urban areas, other settlements, and croplands (Miraldo *et al.*, 2016; see **Figure 2.2.2F** in Section 2.2.3.1). A synthesis comparing genetic diversity estimates from wild populations facing different direct drivers found that populations whose habitat had been fragmented by land-use change have around 17% less genetic diversity than undisturbed populations (DiBattista, 2008); that study found no effect of direct exploitation on genetic diversity, but another meta-analysis reported that populations of fish species that have been overfished in the last 50 years had significantly lower genetic diversity than populations of closely related species (Pinsky & Palumbi, 2014). The declines in range size, numbers of populations, and population sizes of many species (Section 2.2.5.2.4) will all tend to reduce their genetic diversity (Frankham, 1996).

Many farmed and domesticated plants and animals have lost genetic diversity through the extinction of races and varieties. By 2016, 559 of the 6190 domesticated breeds of mammal were recorded as extinct (including 182 breeds of cattle, 160 of sheep and 108 of pig), as well as 84 of the 2632 domesticated breeds of bird (including 62 chicken breeds and 15 breeds of duck) (FAO, 2016b). A further 1500 breeds (999 mammals and 501 birds) are currently threatened with extinction (FAO, 2016b). These numbers are sure to be underestimates as the conservation status of 58% of breeds remains unknown (FAO, 2016b). Modernization of agriculture has sharply reduced both the numbers of crop species and numbers of varieties of those species that are cultivated (Esquinas-Alcázar, 2005).

Losses of genetic variation can be permanent, or nearly so, because the forces that deplete variation (extinction, small population size, inbreeding, natural selection) typically work much more quickly than do the forces replenishing variation (speciation, mutation, recombination, gene flow). For example, the cheetah (*Acinonyx jubatus*) still shows genetic evidence of a population bottleneck around 12,000 years ago, around the same time that many other large mammals were extirpated from the area (Dobrynin *et al.*, 2015). Similarly, hunting and land-use change have extirpated many genetically unique populations of the black rhinoceros (*Diceros bicornis*), with the loss of over two thirds of its historical mitochondrial genetic variation (Moodley *et al.*, 2017); and the fur seal (*Arctocephalus gazella*) still has little among-population genetic variation after the commercial sealing in the 18th and 19th centuries caused populations to crash (Wynen *et al.*, 2000).

Direct drivers have commonly been shown to reduce phylogenetic diversity (PD: Faith, 1992), a measure of genetic diversity among species. In the Brazilian Caatinga, plant communities in sites that have undergone more disturbance (e.g., selective logging, fuelwood extraction and grazing) have lower PD than communities in less disturbed sites (Ribeiro *et al.*, 2016). Costa Rican bird communities living on intensively farmed land have 900 million years less PD than those in natural forest, and 600 million years less than those on diversified agricultural land (Frishkoff *et al.*, 2014). Worldwide, bird assemblages in highly urbanized habitats average 450 million years less PD than those in natural habitats nearby, mainly because of local extinctions (Sol *et al.*, 2017). In some contexts, gains in PD from alien species has outweighed the PD losses from local extinctions, as in Pacific Oceanic island assemblages of flowering plants (Carvallo & Castro, 2017).

Knowledge gaps: Global synthesis of patterns and trends in genetic composition is still at an early stage, with analyses so far having limited taxonomic or geographic coverage.

2.2.5.3 Status and trends of nature in land and sea managed and/or held by Indigenous Peoples and Local Communities

2.2.5.3.1 Status and trends of nature as assessed by science

(N.B. Italics denote indicators that are plotted, for indigenous lands and for the world as a whole, in **Figures 2.2.8** or **2.2.13**)

Indigenous lands have ecosystems that are more structurally intact, and ecological communities that are more compositionally intact, than the global average for terrestrial regions; and their intactness is declining more slowly. Around half of the indigenous land mapped by Garnett *et al.* (2018) is still *primary vegetation*, compared with a global average of only 39% (Hurtt *et al.*, 2018); only 7% is cultivated or urban (global average = 24%) (ESA, 2017); and two thirds is classed as 'natural' (Human Footprint score < 4), compared with only 44% of other lands (Garnett *et al.*, 2018). The *Biodiversity Intactness Index* (BII) (Hill *et al.*, 2018) averages 85% on indigenous lands (versus 79% globally); a more fine-grained of BII estimate for tropical and subtropical forest biomes (*tropical forest BII*) (De Palma *et al.*, 2018) gives a lower estimate for average BII in indigenous lands (68%), but still higher than the global average for these biomes (62%); and *Mean Species Abundance* averages 85.5% in Indigenous Lands (versus

76.1% globally). These indicators also tend to be declining markedly more slowly in indigenous lands than across the globe as a whole (at 33% of the global rate for the loss of *land that is not cultivated or urban*, and 68% of the global rate of loss of *tropical forest BII*).

Many of the worlds' healthiest ecosystems, and a significant proportion (and in many regions the majority) of natural land outside protected areas, are within IPLC lands (Garnett *et al.*, 2018; Porter-Bolland *et al.*, 2012). Several studies indicate that IPLCs reduce deforestation rates (e.g., Genin *et al.*, 2013; Porter-Bolland *et al.*, 2012). However, to date there is not enough evidence for the conservation advantages of community-based forest management, and more quantitative case studies are needed to demonstrate causal relationships (Bowler *et al.*, 2010; Rasolofoson *et al.*, 2015).

No global analysis of agrodiversity trends on IPLC lands is yet available, but some biodiversity-rich lands (e.g., under shifting cultivation) have been converted to large-scale industrial food and biofuel production (Heinimann *et al.*, 2017); and global trade increases the land area under cash-crop cultivation, decreasing local crop diversity, and pushing people to deforest, make a living on marginal areas or overexploit local biodiversity (Wolff *et al.*, 2017). Nonetheless, lands managed and held by IPLCs have often kept, despite agricultural modernization, a high diversity of genetic resources such as adaptive varieties and breeds (Jarvis *et al.*, 2008).

2.2.5.3.2 Trends of nature as observed by Indigenous Peoples and Local Communities

IPLCs often monitor changes not only of their key natural resources but also of other salient features of nature at the population, ecosystem and landscape levels, giving them a deep understanding of multi-decadal trends in nature (Sterling *et al.*, 2017). For example, IPLCs will often closely monitor introduced species that significantly affect natural resources important for them (e.g., Aigo & Ladio, 2016; Lyver *et al.*, 2017; Periago *et al.*, 2017), often before they become sufficiently widespread to attract the attention of natural scientists. Culturally, ecologically or morphologically salient (cf. Hunn, 1991) species are often monitored closely as well (Fernández-Llamazares *et al.*, 2016; Giglio *et al.*, 2015; Lykke, 2000). Pastoralists frequently mention trends of populations of palatable or unpalatable species; e.g., in Europe (Fernández-Giménez & Estaque., 2012; Molnár *et al.*, 2017); in Asia (Behmanesh *et al.*, 2016; Bruegger *et al.*, 2014; Hopping *et al.*, 2016; Kakinuma *et al.*, 2014); in Africa (Admasu *et al.*, 2010; Angassa & Beyene, 2003; Assefa & Hans-Rudolf, 2016; Oba & Kaitira, 2006; Oba & Kotile, 2001). Ecological indicators developed and used by IPLCs are often biocultural, having both social and cultural dimensions (Sterling *et al.*, 2017). Some of these indicators are compatible with indicators used by scientists such as those related to species composition, vegetation structure and phenological traits (cf. Danielsen *et al.*, 2014; Harmsworth *et al.*, 2011; Nursey-Bray & Arabana Aboriginal,

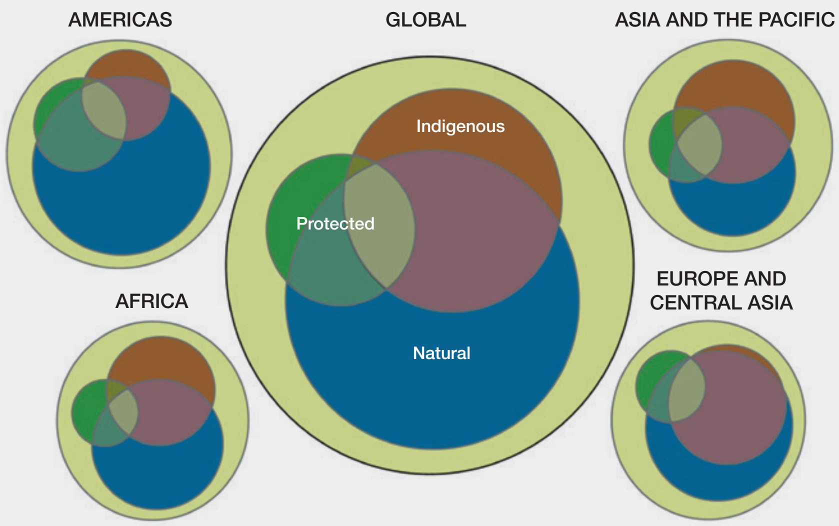

Figure 2 2 20 **Intersections among indigenous lands, protected areas and natural (Human Footprint score < 4) landscapes (see following sections) globally and for each IPBES region.**

Circles and intersections are all proportional to area with the largest circle scaled to the land area of the Earth (excluding Antarctica) (Garnett *et al.*, 2018).

2015). Other indicators, typically those with deeper social and cultural meaning, are less compatible. The selection of elements of nature monitored by IPLCs may be influenced by conservation and national policies (TEBTEBBA Foundation, 2008).

Of the approximately 470 indicators and related 321 trend records reported in the reviewed literature, 72% showed negative trends **(Figure 2.2.21)**. Many of these (e.g., negative trends of species populations – 27.6%, negatively perceived trends regarding species composition change – 9.5%) are connected directly or indirectly to changes in nature's contributions to people that make living from nature more difficult for IPLCs **(Figure 2.2.21B)**. The indicators are distributed unevenly among the unit of analysis, but over half the trends are negative except in tundra habitats **(Figure 2.2.21A)**.

The main global trends were as follows:

- Resource availability is generally decreasing, whereas time needed or distance travelled to harvest resources is increasing (e.g., Lyver *et al.*, 2017; Posey, 1999), especially in boreal forest and tundra habitats where distribution and abundance of salient game species is changing due to climate change (Fienup-Riordan *et al.*, 2013; Huntington *et al.*, 2016; Naves, 2015).

- Declines or increases in wild species populations are among the most common indicators in almost every unit of analysis (26.6%, but 32.8% if indicators about their accessibility is also included), with culturally salient species often showing negative population trends (mainly plants, mammals, birds, fishes and insects, e.g., Aswani *et al.*, 2015; Bruegger *et al.*, 2014; Cuerrier *et al.*, 2015; Reis-Filho *et al.*, 2016; Reyes-García *et al.*, 2016).

- IPLCs have observed many native newcomer species arriving to their area as climate changes (e.g., southern species to boreal/arctic areas), but also the arrival and spread of new pests and aggressive alien species (e.g., Aigo & Ladio, 2016; Cuerrier *et al.*, 2015; Jandreau & Berkes, 2016; Lyver *et al.*, 2017).

- IPLC indicators recognize an increase in natural habitat loss, especially forests and grazing lands (e.g., Admasu *et al.*, 2010; Ancrenaz *et al.*, 2007; Calvo-Iglesias *et al.*, 2006; Jandreau & Berkes, 2016; Kimiti *et al.*, 2016; Turner & Clifton, 2009), while remnant ecosystems appear to be degrading and their biomass production decreasing (e.g., opening up of forest canopy; less biomass, more annuals and shrubs on pastures; proportion of unpalatable plants on rangelands; e.g., Admasu *et al.*, 2010; Angassa & Beyene, 2003; Assefa & Hans-Rudolf, 2016; Behmanesh *et al.*, 2016; Bruegger *et al.*, 2014; Jandreau & Berkes, 2016)).

- IPLCs have observed that the condition of wild animals appears to be deteriorating and their sizes decreasing (e.g., Giglio *et al.*, 2015; Huntington *et al.*, 2016; Moller *et al.*, 2004; Naves, 2015; Parlee *et al.*, 2014; Wong & Murphy, 2016)).

Box 2 6 Indicators of nature used by Indigenous Peoples and Local Communities.

Unlike many scientific indicators that try to maximize broad comparability and therefore try not to be influenced by local context, IPLC indicators are often more closely linked to human-nature relations (Sterling *et al.*, 2017) and are holistic in nature (Berkes, 2012; Inuit Circumpolar Council, 2015; Posey, 1999). Many IPLC indicators are locally tested, are intended to be locally relevant (TEBTEBBA Foundation, 2008), and go back for decades (Huntington *et al.*, 2005; Mantyka-Pringle *et al.*, 2017; Turner & Clifton, 2009). IPLCs, with a longer baseline of personal experience with the environment, may be more aware of shifts in nature (cf. changes in the Arctic, the bias in monitoring protected area management effectiveness; Corrigan *et al.*, 2018). Some cultural memories go back hundreds or even thousands of years (Nunn & Reid, 2016). Furthermore, local observations may cover many less studied, remote habitats and regions that often present environmental or technical inconveniences for scientists (Fienup-Riordan *et al.*, 2013; Huntington *et al.*, 2005). Finally, local monitoring systems are often independent from formal projects and financial limitations.

However, IPLCs monitoring data also have drawbacks for regional and global assessments. Notably, they are often non-quantitative and follow a fuzzy logic (Berkes & Berkes, 2009; Reyes-García *et al.*, 2016) so are less compatible with scientific monitoring protocols. Data on local trends are scattered among thousands of Indigenous Peoples and Local Communities, and the diverse sets of locally adapted indicators are even more difficult to synthesize globally than scientific data. IPLCs and scientific data, however, may often efficiently complement each other in helping to understand local impacts of global changes (Huntington *et al.*, 2005; Reyes-García *et al.*, 2016; Turner & Clifton, 2009).

A more detailed global synthesis of IPLC-observed trends in nature is hindered by the inherent challenges in this process, such as obtaining properly acquired Free, Prior and Informed consent (FPIC), the time required for adhering to local community protocols, and the lack of centralized institutions for hosting, aggregating and analyzing data of IPLCs in culturally appropriate ways.

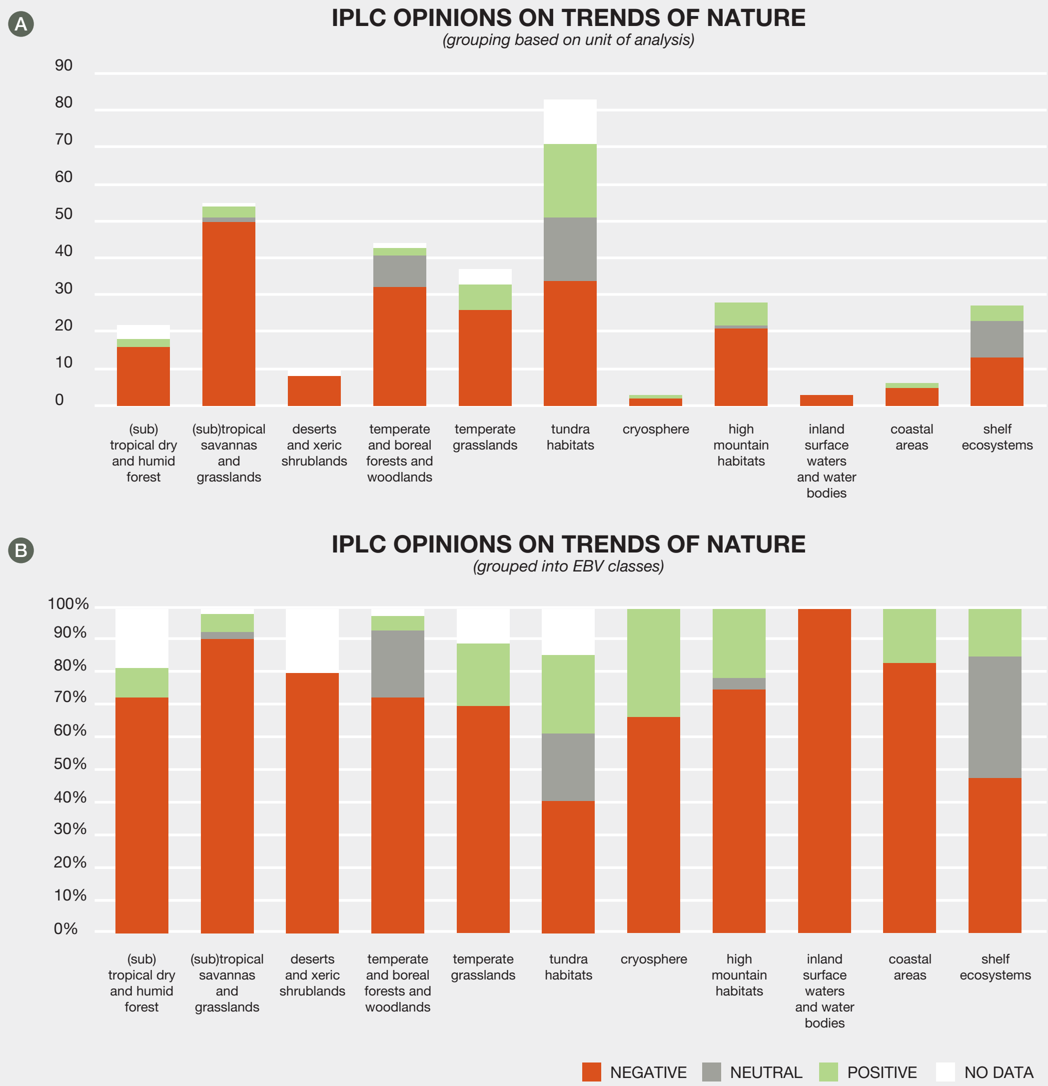

Figure 2 2 21 **Opinions on trends in nature as assessed by Indigenous Peoples and Local Communities using their own indicators, split into A main ecosystem types (mostly unit of analysis), and B per Essential Biodiversity Variable class.**

The analysis is based on 321 trend records published in 54 publications found in a systematic review (see Supplementary Material). No data was found on genetic diversity of wild species. Opinions, whether the trends impact IPLCs in a positive, neutral or negative way, were based on local understandings of the trend, but only if it was explicitly documented in the sources. No data: no opinions on trends were provided by the publication. (Source: IPBES)

2.2.6 GLOBAL-SCALE ANALYSIS OF ATTRIBUTION OF TRENDS TO DRIVERS

2.2.6.1 Challenges of synthesis

This section focuses on attributing temporal changes in the state of nature to the set of direct drivers described in Sections 2.1.13–2.1.17 in chapter 2.1, and the findings presented below are based on two extensive systematic reviews. The first (see Supplementary Material, Appendix AA for methodology) is a synthesis of natural science studies that have assessed and compared the impacts of at least two direct drivers on indicators reflecting the state of nature. This synthesis examined nearly 4000 studies and databases identified as potentially relevant, retaining 163 priority non-redundant sources (listed in Supplementary Material, Appendix BB); priority was given to large-scale studies (preferably global, but also continental or regional ones), but local studies were used when no large-scale studies were available. The second synthesis (see Supplementary Materials, Appendix CC for methodology) examined how IPLCs attribute trends in nature to direct drivers. This examined 6,136 studies, retaining 192 for analysis (see details in Appendix CC). Studies were excluded from this IPLC-focused synthesis if they focused only on science-based indicators or considered community-based monitoring programmes without using locally developed indicators. The two syntheses therefore use extensive but complementary evidence bases.

Synthesizing the attribution of changes in the state of nature to direct drivers is not straightforward. The complexity and high dimensionality of nature (Section 2.2.3) mean that many indicators are needed to capture trends (Sections 2.2.3 and 2.2.5); but indicators can differ in their metrics, sampling methods, spatial and temporal scales and resolutions, taxonomic groups, realms and regions (Section 2.2.5). These syntheses therefore organize indicators using the same Essential Biodiversity Variable (EBV: Pereira *et al.*, 2013) framework as used in Sections 2.2.3 and 2.2.5, aggregating information across multiple indicators within each EBV class for robustness and generality. Specific patterns are reported for some indicators having sufficient reliable information.

There are a range of ways of comparing the importance of different drivers. For example, prevalence-based attribution can be used with IUCN Red List assessments, estimating the commonness of each driver among the listed threats (e.g., Salafsky *et al.*, 2008; Vié *et al.*, 2009). By contrast, Mean Species Abundance (MSA; Alkemade *et al.*, 2009) lends itself to effect-based attribution, because it is estimated by combining independent driver-specific dose-response models with global data on driver pressure intensity. These two approaches are in principle not directly comparable because, e.g., a driver could affect all of a set of species without being the strongest threat to any. In order to include as wide a range of studies as possible, these syntheses have assumed prevalence-based attribution to be a reasonable approximation of effect-based attribution.

Another challenge is that studies often use threat classifications that differ from each other and from the one used in this assessment. As far as possible, threats reported in the literature were allocated to one of the five major direct drivers used in this assessment (chapter 2.1 Sections 2.1.13–2.1.17); an additional category, 'Other', was used for threats that do not fit clearly into these categories, such as fire or direct human disturbances due to recreational activities.

Many studies ranked the importance of drivers instead of assessing their importance in terms of relative magnitude. Provided that the threat classification system is a good match to the one used here, this qualitative information was used and converted into quantitative estimates using a systematic approach (Hosonuma *et al.*, 2012; see details in Appendix AA).

Although IPLCs usually possess a deep understanding of the impact of direct drivers on nature due to their closeness and direct dependence on nature for their livelihoods (Luz *et al.*, 2017; Reyes-García *et al.*, 2014), combining IPLC-observed driver information with natural science data presents additional problems. IPLC attribution is typically less quantitative, more scattered (geographically and thematically), and harder to aggregate globally; but provides unique insight into how drivers affect aspects of nature directly related to local livelihoods.

Section 2.2.6.2 presents the relative impacts of the different direct drivers on changes in different aspects of nature at the global level, for each of the four IPBES regions (Americas, Europe and Central Asia, Africa and Asia and the Pacific) and for each of the three global biogeographic realms (i.e., terrestrial, freshwater and marine), based on natural science indicators **(Figure 2.2.22)**. The attributions of drivers by units of analysis are not presented here, mainly because many of the indicators considered do not have information broken down at that level. Moreover, the amount of information collected does not allow for a sufficiently robust analysis such as that presented at the level of regions and realms. Therefore, attributions of drivers within each units of analysis are described in Section 2.2.7 on the basis of relevant and comprehensive bibliographic references compiled by the authors. Section 2.2.6.3 then synthesizes the perceptions of IPLCs about the drivers behind changes in local IPLC indicators within different types of ecosystems.

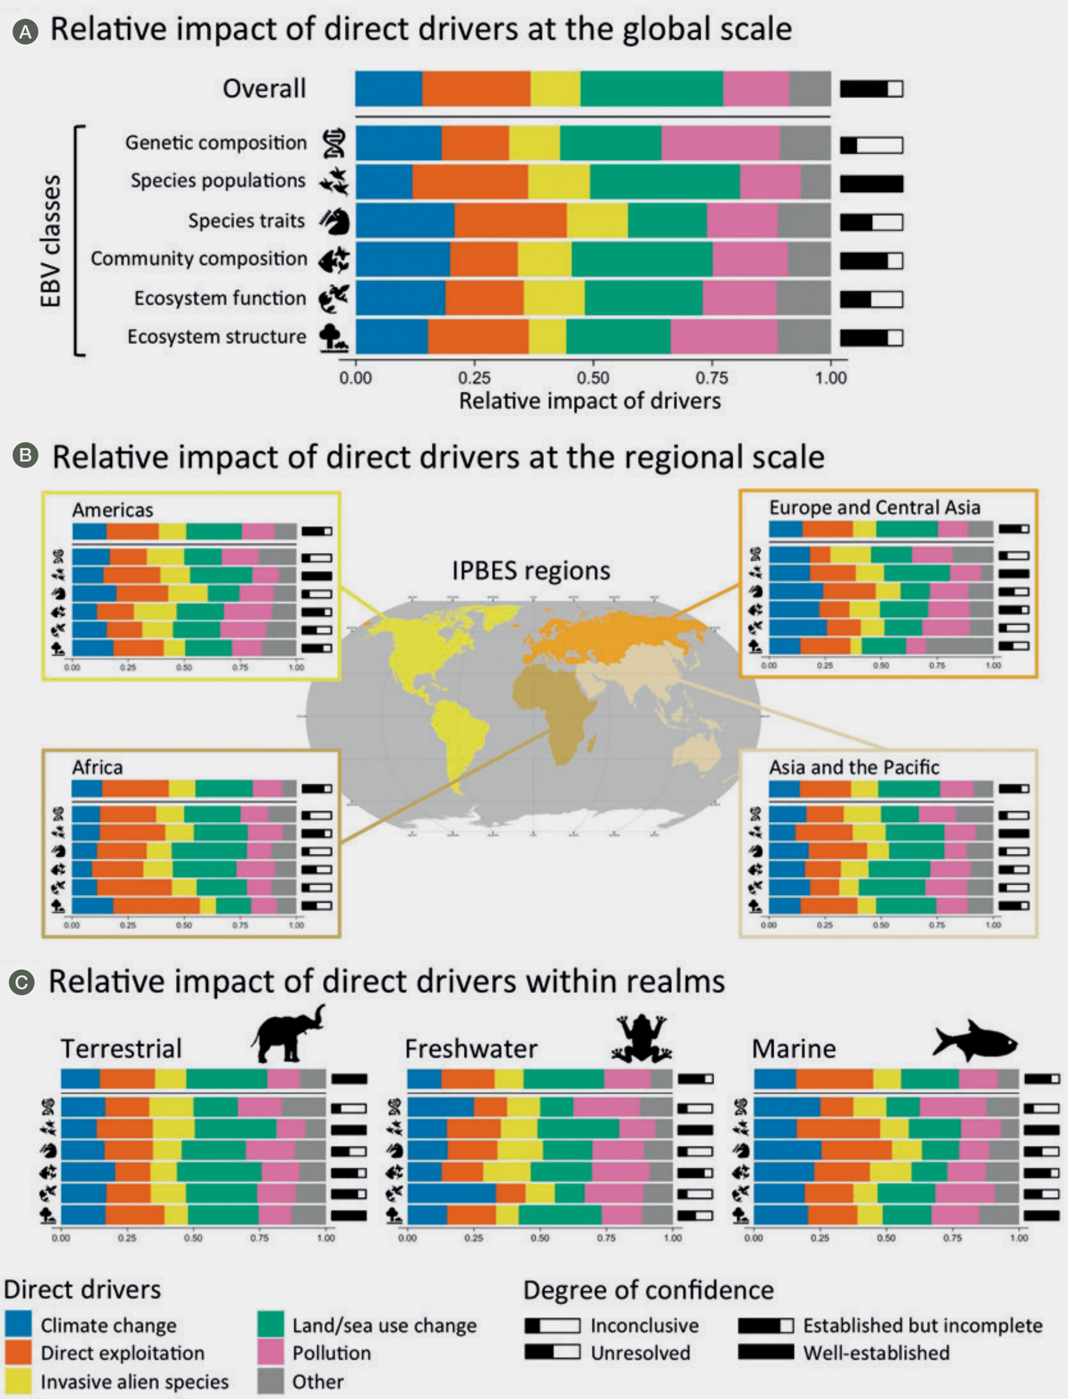

Figure 2 2 22 **Relative impact of direct anthropogenic drivers (colour bars) on the state of nature at the global scale A, within each IPBES region B and for terrestrial, freshwater and marine realms C.**

The top row in each panel shows the overall pattern including all the indicators used in the analysis. The next rows show the patterns for each of the six classes of Essential Biodiversity Variables (EBV), each represented by several indicators. The width of each colour bar indicates the estimated relative importance of each driver in changing the state of nature but should not be interpreted as an absolute magnitude of the impact of each driver because both qualitative and quantitative information was combined in the analysis (see details in the main text). The degree of confidence shown alongside each row (more black = more confidence) reflects the quantity and quality of information available in the literature to estimate the relative impact of different drivers at the corresponding level of analysis (see confidence framework in chapter 1). Note that the top row in each panel is not a simple average across the different EBV classes: some classes include more indicators and/or more studies than other classes (see degree of confidence) so have a higher weight in the estimations. A full list of studies synthesized in this figure is provided in Appendix BB, and the methodology is described fully in Appendix AA. Credits for icons: EBV classes icons created by Cesar Gutiérrez of the Humboldt Institute –Bogotá, Colombia- for GEO BON; icons for realms provided by WWF.

The relative global importance of direct drivers also varies among indicators within EBV classes, as shown in **Figure 2.2.23** for a set of specific indicators for which sufficient information was available. Further discussion on these indicators is presented in Appendix DD.

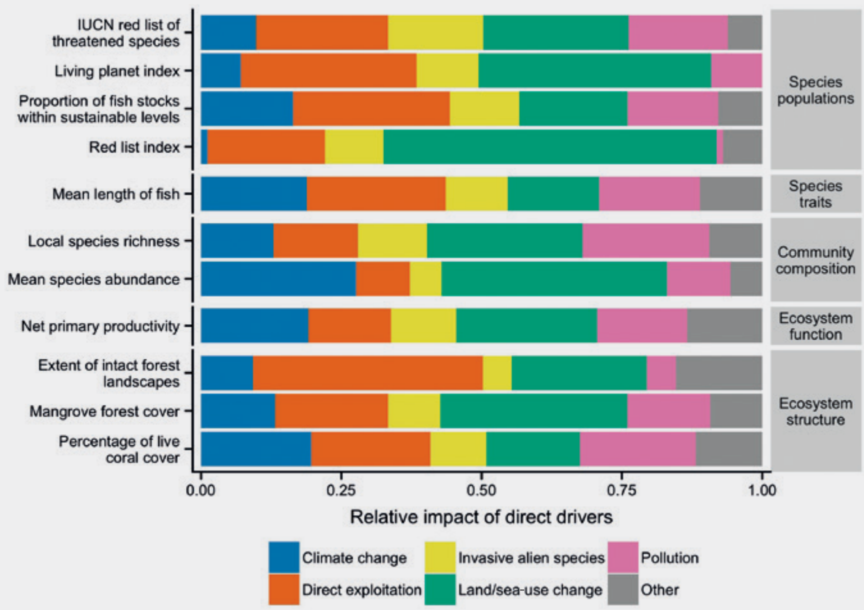

Figure 2 2 23 **Relative impact of direct anthropogenic biophysical drivers (colour bars) on selected indicators of the state of nature for which sufficient representative information was available.**

Indicators are grouped according to the Essential Biodiversity Variable (EBV) framework (see right-hand side), except that no indicators were available for the EBV class *Genetic composition*. The driver category "Other" includes threats that do not clearly belong to any of the five main drivers (e.g. fire, human disturbance, recreational activities, and tourism). The width of each colour bar indicates each driver's estimated relative importance in changing the state of nature (see details in the main text and in **Figure 2.2.22**). Further discussion on these individual indicators is included in Appendix DD.

2.2.6.2 Attribution of natural science indicator trends to direct drivers

Land/sea-use change is the most important direct anthropogenic driver of change in the global state of nature, with a relative impact of 30%, followed by direct exploitation (23%), climate change (14%), pollution (14%) and invasive alien species (11%) **(Figure 2.2.22A)**. Threats not clearly aligned to any of these five main drivers (e.g., fire, human disturbance, recreational activities, and tourism) account for the remaining 9%.

The relative global importance of drivers varies considerably among the five EBV classes where robust comparisons could be made (too few studies assessed the relative impact of drivers of change in *Genetic composition* for comparisons to be robust) **(Figure 2.2.22A)**. Land/sea-use change is the most important driver of change for three of the five remaining EBV classes and is particularly important for *Species populations* (31.5%). Pollution is very slightly more important than land/sea-use change (22.5% versus 22%) in driving changes in *Ecosystem structure* but is not in the top two drivers for other EBV classes. Direct exploitation is the most important driver of changes in *Species traits* (23.5%), with climate change second (21%). Climate change is also second for *Community composition* and *Ecosystem function*.

The four IPBES regions largely reflect the global pattern **(Figure 2.2.22B)**, but there are some regional differences. In

Africa, the impact of direct exploitation (30%) exceeds that of land/sea-use change (25.5%). In the Americas, these two drivers have a similar impact (23.5 and 25%, respectively). In the other two regions, land/sea-use change is the most important driver of change in the state of nature.

Each IPBES region shows considerable variation among EBV classes. For example, direct exploitation has the highest impact on *Ecosystem structure* in Africa, whereas other threats (i.e., fires) are particularly important in Europe and Central Asia **(Figure 2.2.22B)**. Although climate change is not the dominant driver across EBV classes in any of the IPBES regions, it has a particularly high impact on *Species traits*, *Community composition,* and *Ecosystem function* in Europe and Central Asia.

Land-use change has had the largest relative negative impact on nature in the terrestrial and freshwater realms (30.5% in both cases), mainly through habitat loss and degradation, whereas in marine ecosystems, direct exploitation of organisms (mainly fishing) has had the largest relative impact (29%) **(Figure 2.2.22C)**. Direct exploitation is the second most important driver in both terrestrial (21%) and freshwater (20%) ecosystems. Climate change is not amongst the two most important drivers of change in any of the realms. In freshwater environments, pollution (17.5%) is more important than climate change (13%) whereas these two drivers have a similar impact (15% and 16%, respectively) in marine systems.

Within each realm there is considerable variation among EBV classes **(Figure 2.2.22C)**. In terrestrial ecosystems, the greatest impact of land/sea-use change is on *Species populations* (31%) and *Community composition* (32%). In freshwater ecosystems, this driver particularly affects *Species populations* and *Ecosystem structure* (both 31%). For marine ecosystems, the highest impact of direct exploitation is on *Species populations* (31.5%). Climate change's strongest impact on land is on *Community composition* (20%); in freshwater it is on *Ecosystem function* (33%) (but with a low degree of confidence); and in the marine realm it most affects *Species traits* (25.5%). Even if their overall importance is limited in all the realms, invasive alien species are markedly impacting some aspects of biodiversity, such as *Community composition* in freshwater ecosystems (18%).

2.2.6.3 Attribution of drivers by Indigenous Peoples and Local Communities

The two most important drivers of changes in nature observed by IPLCs are land/sea-use change and climate change **(Figure 2.2.24)**. Land-use change includes mainly conversion to intensive agriculture, urbanization and discontinuation of traditional land management practices. For example, land-use change and expansion

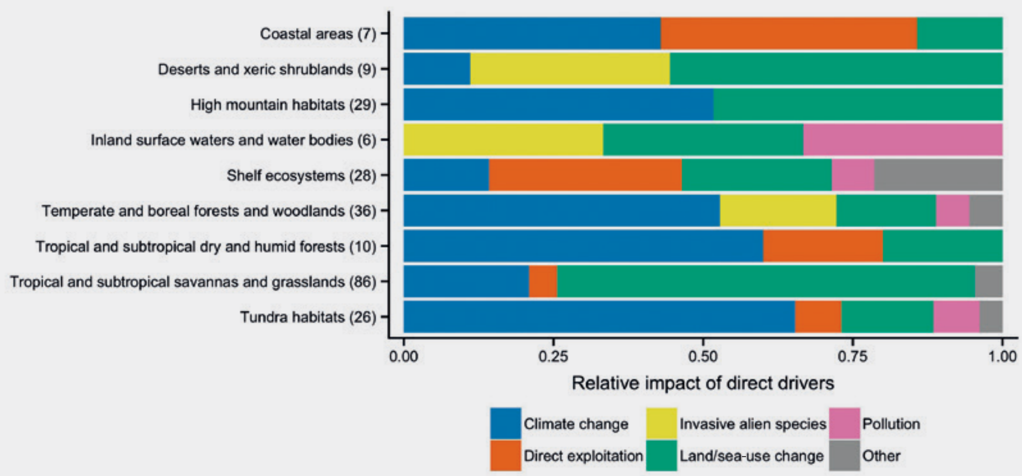

Figure 2 2 24 **Attribution of changes in different ecosystems (rows) to direct drivers (colour bars) compiled from IPLC observations worldwide based on 470 reviewed local IPLC indicators (see Appendix CC).**

Numbers in brackets are numbers of indicators with driver attribution. Relative impact of direct drivers is shown as their relative frequency in the reviewed studies. The category "other" includes threats that were identified for some ecosystems during the collection of data but are not clearly linked to the five main categories (e.g. vegetation encroachment, disease and insect outbreaks).

of settlements (urbanization) are the direct drivers of change in rangelands most often mentioned by IPLCs in a number of African regions (Admasu *et al.*, 2010; Assefa & Hans-Rudolf, 2016; Jandreau & Berkes, 2016; Kimiti *et al.*, 2016).

Discontinued traditional land management practices (abandonment) were observed as direct causes for some changes to vegetation structure (e.g., bush encroachment, reforestation; Babai *et al.*, 2014; Oba & Kotile, 2001; von Glasenapp & Thornton, 2011). Climatic changes, such as droughts and the increasingly unpredictable annual distribution of rainfalls, are important observed reasons for the decreasing biomass production and changes in vegetation structure of rangelands, which often require reorganization of traditional grazing regimes (e.g., Admasu *et al.*, 2010; Assefa & Hans-Rudolf, 2016; Duenn *et al.*, 2017; Kakinuma *et al.*, 2008). Altered rainfall patterns, which can influence behaviour patterns of wild animals (e.g., game or migration patterns of birds; Ingty, 2017; Kimiti *et al.*, 2016; MacDonald *et al.*, 2013; Turner & Clifton, 2009), are also seen as important drivers of change.

Deliberate or unintentional introduction of new species can also be direct drivers of changing species pools in different habitats (e.g., inland water bodies, wetlands; Aigo & Ladio, 2016; terrestrial habitats: Lyver *et al.*, 2017; Periago *et al.*, 2017). IPLCs report invasive alien species affecting a wide range of taxonomic groups (e.g., plants, fishes, birds; Aigo & Ladio, 2016; Lyver *et al.*, 2017; Periago *et al.*, 2017; Waudby *et al.*, 2012). Overexploitation was the most often reported driver for deterioration of pasture land and tropical forests at the agricultural frontiers (e.g., Aswani *et al.*, 2015; Fernández-Llamazares *et al.*, 2016). Local overharvesting by companies or by local fishers motivated by commercial trade were mentioned by artisanal fishers as drivers of observed decreasing fish stocks (Aswani *et al.*, 2015; Carr & Heyman, 2012; Giglio *et al.*, 2015; Reis-Filho *et al.*, 2016).

2.2.7 UNITS OF ANALYSIS

2.2.7.1 Introduction

The Units of Analysis for the Global Assessment are a broad-based classification system at the global level, considering both the state of nature in classes equivalent to biomes, and in anthropogenically-altered biomes or 'anthromes'. The units correspond broadly to global classifications of nature and human interactions, serving the need for analysis and communication in a global policy context. The list of 17 global Units of Analysis includes 13 biomes (7 terrestrial, 2 freshwater, 3 marine and one cuts across all three) and 4 anthromes (see chapter 1 and **Figure 2.2.2A**). All terrestrial biomes except for the cryosphere have been settled and populated by IPLCs historically, and increasingly by modern societies. The freshwater biomes reflect a simple split in relation to depth and vegetation, i.e., coarse function, and the marine biomes reflect the most basic division of oceans by depth and proximity to land. Nevertheless, the biomes reflect relatively well-known properties and variation in nature across the globe and coproduction of NCP by people. Biomes are the lungs, heart, production center, skin and kidneys of planet earth. They cycle carbon, nitrogen and other elements; provide food and materials; process waste.

The biomes vary in state from unaltered to highly altered or degraded. The addition of anthropogenic drivers of decline to natural disturbances can impose significant cumulative impacts on biomes, with complex interactions. Some biomes remain unmodified in only a small fraction of their former range; e.g., in most regions, nearly all temperate forest has been altered or is under active human management. There is considerable variation among and within regions, and among and within biomes. Some biomes have experienced positive changes recently, as land-use practices reverse; boreal forest area has been stable for decades, while temperate forest area has expanded 10% since 1990.

Anthromes are highly altered biomes, defined by humanity's monopolization and/or maximization of one or more NCP (i.e., distinct from degraded biomes). The main drivers of biome conversion to anthromes include large-scale commercial agriculture, local subsistence agriculture, urban expansion, construction and mining. The anthromes layer over biomes (e.g., a city in a grassland area), but some so transformed the original biome no longer exists there. Two anthromes are exclusively terrestrial, reflecting where people live and channel biological productivity to serve needs through food, timber and other types of production. In temperate biomes, conversion to anthromes and deterioration has slowed to zero or even reversed with active

Table 2 2 2 **Overview of some of the features on the IPBES Units of Analysis.**

Unit Name	Unit ID	Area (mSqKm)	NPP (gC/m2/ year x10^6)	Average Relative Species Richness	Population (millions of people)	Urban Areas (Unit 9)		Cultivated Areas (Unit 10)	
						mSqKm	% of unit	mSqKm	% of unit
Tropical and subtropical dry and humid forests	1	23.49	64	0.51	2,880	0.13	0.6%	6.83	29.1%

Notes:
Empty cells show where numbers are not applicable
All values are in 2015, unless otherwise noted.
+ Area of terrestrial cryosphere = 17.71 mSqKm. Arctic and Southern Ocean annual sea ice extent has averaged 22.59 mSqKm for the ten years from 2008–2017.
* Same as/included in Unit 15
** Units have no calculable area. There are no databases for aquaculture locations (terrestrial, freshwater and marine) from which area can be calculated. 'Intensely and multiple used coastline' is currently undefined in terms of area, as the coastline is a linear feature. Global datasets are also not available for estimating its length or area.

restoration. However, in tropical biomes, where both human population and economic growth are high, conversion rates are still high. The aquaculture and intensively developed coastline anthromes cut across terrestrial, freshwater and marine systems, and conversion of marine biomes to anthromes is at its early stages. Both aquaculture and the intensively/multiply used coastlines are likely at an early stage of acceleration (see descriptions below), and no datasets currently exist to estimate their area.

The attribution of drivers presented in this section are based on key references identified by the authors for each unit of analysis and is therefore different and complementary to that in Section 2.2.6, which shows attributions by IPBES regions and by realms based on a global-scale systematic review of literature.

2.2.7.2 Tropical and subtropical dry and humid forests

Tropical and subtropical forests cover about 52% of global forested land (FAO, 2015a; Keenan *et al.*, 2015), holding an aboveground carbon stock of 190–220 billion tons (Baccini *et al.*, 2012; Liu *et al.*, 2015; Saatchi *et al.*, 2011), representing about 70% of the carbon in forests globally (Yingchun *et al.*, 2012), and 35% of terrestrial GPP (Beer *et al.*, 2010). These ecosystems harbor the greatest biological diversity globally, containing for example the ten hotspots with the greatest total number of endemic higher terrestrial vertebrates (Mittermeier *et al.*, 2011, 2004) and the greatest number of threatened species.

This Unit plays a vital role in local to global climate regulation, through complex hydrological and biogeochemical dynamics, mainly of CO_2 and water vapor (Bonan, 2008). The Amazonian rainforest keeps the air humid for over 3,000 km inland (Salati *et al.*, 1979), and transpires twenty billion tons of water daily (Nobre, 2014).

Globally, tropical and subtropical forest area has declined from 1990–2015. All top ten countries reporting the greatest annual net loss of forest area for 2010–2015 belong to this Unit (FAO, 2015a). The rate of loss of tropical forests was 10.4 M ha yr^{-1} in the 1990s, slowing to 6.4 M ha y^{-1} in 2010–2015 (Keenan *et al.*, 2015). For subtropical forests these numbers were 0.4 M ha yr^{-1} and 0.0 M ha yr^{-1}, respectively. These averages mask high variance between regions, as well as within regions and countries, with highest losses in South America and Africa (Hansen *et al.*, 2013). For example, while Brazil showed a reduction in annual forest loss from 2000–2012, increases were measured in all other regions.

Land-use change is the main driver of forest loss in tropical and subtropical regions (FAO, 2016c; Meyfroidt & Lambin, 2011; Newbold *et al.*, 2014); other subdrivers vary in importance among and within regions (Boucher *et al.*, 2011; DeFries *et al.*, 2010; FAO, 2016c). Overall, the main cause of deforestation is large-scale commercial agriculture (e.g., cattle ranching, oil palm, soy, and cocoa) (40% of deforestation), followed by local subsistence agriculture (33%), urban expansion (10%), infrastructure (10%) and mining (7%) (FAO, 2016c; Hosonuma *et al.*, 2012). Forest degradation is driven mainly by timber and logging (58%), fuelwood/charcoal (27%), uncontrolled fires (10%), and urban expansion (5%). Recognition of IPLCs' territories helps buffer deforestation in the Amazon (Soares-Filho *et al.*, 2010), and local farmer communities can contribute to reforestation (Jacobi *et al.*, 2013).

Habitat loss and degradation are the main causes of reductions in species richness and abundance (Newbold *et al.*, 2014; WWF, 2016), while habitat conversion and harvesting are the main threats to Threatened plant species in tropical forests (Brummitt *et al.*, 2015). Main trends perceived by IPLCs include the loss (or introduction) of salient large mammals (e.g., elephant, peccary) (Ancrenaz *et al.*, 2007; Sahoo *et al.*, 2013) and the proliferation or collapse of plant species (e.g., medicinal plants; Fernández-Llamazares *et al.*, 2016).

Tropical and subtropical regions are projected to experience extreme climatic conditions earlier than other regions, such as boreal forests, tundra and taiga (Beaumont *et al.*, 2011). Extreme climate events in the last two decades (Chen *et al.*, 2010; Marengo *et al.*, 2013; Satyamurty *et al.*, 2013), interacting with other factors such as deforestation and fire, have caused large-scale long-lasting impacts on forest structure and function, affecting hydrological and carbon cycles (Davidson *et al.*, 2012; Qie *et al.*, 2017).

Positive trends in forest cover are reported in thirteen tropical and subtropical countries containing 6.4% of global tropical and subtropical forest area (Supplementary Material S2.2.2.4). These countries have transitioned from net forest loss to net gain, mainly driven by planted-forest expansion (FAO, 2016c; Keenan, 2015; Sloan & Sayer, 2015).

2.2.7.3 Boreal and temperate forests

Boreal and temperate forests comprise one third and a quarter of global forest cover, respectively (FAO, 2015a), covering 1.91 billion ha (FAO, 2015a). They experience a cold continental climate, with a growing season of <130 days (temperate) and >140 days (boreal). Boreal forests sustain a low richness of coniferous trees that withstand freezing and extended dormant periods, with two abundant deciduous genera. The temperate zone has many continental endemic deciduous species, with some common genera, such as pines. The boreal biome is primarily in Canada, Russia, and Scandinavia, while the temperate zone occurs in both hemispheres, on six continents. Highly productive temperate rainforests occur on the west coast of North America, Chile, New Zealand, and Australia.

Boreal forest area did not change between 1990 and 2015 (FAO, 2015a) and 43.8% of the remaining global "Intact Forest Landscapes" are boreal (Potapov *et al.*, 2008). Nearly two thirds of boreal forests are currently under management, mostly for timber (Gauthier *et al.*, 2015). Virtually all temperate forests in most regions of the world are managed; temperate China and Europe were largely deforested by the 1500s, many countries have lost > 90% of their forest cover (Kaplan *et al.*, 2009), and there are no large intact or primary forest areas (Krishnaswamy & Hanson, 1999). Temperate forests have increased by about 67 million ha since 1990, largely due to planting in China and farm abandonment globally (Campbell *et al.*, 2008; FAO, 2015a; Keenan *et al.*, 2015; Yin *et al.*, 2005), but young secondary forest is much less rich in biodiversity than primary forest. Over 350,000 km^2 of intact forest landscapes (i.e., large areas of forest or natural mosaic, free from evident signs of human disturbance) were lost from temperate and boreal forests between 2000 and 2013 (Potapov *et al.*, 2017), showing continuing deterioration in the condition of primary forest within this unit of analysis.

The boreal forest is the largest store of terrestrial carbon (Bradshaw & Warkentin, 2015; Gauthier *et al.*, 2015; Pan *et al.*, 2011), over 75% of which is in soil organic matter (Bradshaw & Warkentin, 2015; Rapalee *et al.*, 1998). Boreal forest has sequestered 0.5 Pg C/yr since 1990, accounting for 20% of the annual terrestrial forest carbon sink (Kurz *et al.*, 2013; Pan *et al.*, 2011), but not all boreal forests are sinks owing to increased fires and respiration due to climate change (Hadden & Grelle, 2017). Between 1990 and 2007 temperate forests have stored a net 0.72 Pg C/yr (Pan *et al.*, 2011).

Both biomes are highly susceptible to climate change (Settele *et al.*, 2014), increasing fire risk (Bradshaw *et al.*, 2009), in part because of low boreal productivity and high susceptibility of peat and permafrost soils. Other climate drivers include moisture stress, warmer temperatures, increased insect infestations, N deposition, and CO_2 fertilization (Kint *et al.*, 2012; Silva *et al.*, 2010). Drier, warmer boreal forests will store less carbon due to moisture stress (Ma *et al.*, 2012), becoming a net source of greenhouse gasses (Flannigan *et al.*, 2000, 2009; Kurz *et al.*, 2013), despite increased productivity in northern open taiga forests (Boucher *et al.*, 2017; Goldblum & Rigg., 2010). A warming climate may result in release of the huge carbon store in frozen boreal peat soils (Schaefer *et al.*, 2011). Projections suggest shifts in forest distribution, depending on dispersal ability among tree species (e.g., Soja *et al.*, 2007). Large areas in the boreal forests are inhabited by IPLCs in Eurasia and North America, who report changing animal population trends (e.g., increasing moose, decreasing caribou, decreasing bird species, e.g., geese) and changing migration patterns, due to climate change (Lyver *et al.*, 2017; MacDonald *et al.*, 2013).

Invasive species and diseases have become a major driver of tree mortality in some temperate forests (Adams *et al.*, 2012; Charru *et al.*, 2010), and diseases are a developing problem in plantations (e.g., Sanderson *et al.*, 2012). Some planted trees are invasive in temperate forests, e.g., *Acacia* (Lorenzo *et al.*, 2011; Yelenik *et al.*, 2004). Temperate regions have high numbers of threatened and endangered species, including >500 tree species (Oldfield *et al.*, 1998), and there have been extinctions, including passenger pigeon (*Ectopistes migratorius*). No boreal plant or animal species has gone extinct but there have been national-level extirpations.

2.2.7.4 Mediterranean forests, woodlands and scrub

Mediterranean forests, woodlands, fynbos and scrub are discontinuously spread in five continents and twenty-two countries (Dallman, 1998). They cover 4 million km^2 (2% of total land area) in Southern Europe and Northern Africa (Mediterranean Basin), South Africa (Western Cape), Northwestern America (e.g., California chaparral), Southern America (Chilean matorral), and Southern Australia. These regions harbour an extremely high diversity of species originating from almost all known biogeographic realms of the world including new landraces (Blondel *et al.*, 2010; de Cortes Sánchez-Mata & Tardío, 2016) and include five biodiversity hotspots of global importance (Mittermeier *et al.*, 2011; Myers *et al.*, 2000). Vegetation types are coniferous or (mostly evergreen) broadleaf forests and woodlands, savannas and grasslands, scrublands and mosaic landscapes, resulting from a strong interaction between heterogeneous environmental conditions and a long-lasting influence of human activities (Blondel, 2006). The Mediterranean biome has the second lowest level of land protection among terrestrial biomes (Hoekstra *et al.*, 2005) and is projected to experience the largest future proportional loss of biodiversity (Malcolm *et al.*, 2006; Sala *et al.*, 2000).

Mediterranean terrestrial ecosystems are highly sensitive to the combined effect of global change drivers and specific driving forces, including climate change, land-use transformations and fires (Barredo *et al.*, 2016; Templado, 2014; Valladares *et al.*, 2014). With the particular geology of Mediterranean systems, these changes have resulted in more frequent and intense fires, water scarcity, land degradation and habitat fragmentation. The unit is increasingly becoming vulnerable (Batllori *et al.*, 2013; Klausmeyer & Shaw, 2009) and future outcomes are difficult to predict (Doblas-Miranda *et al.*, 2017, 2015; Voltz *et al.*, 2018). Recent shifts in fire regime modify the composition of the vegetation (from coniferous forests to landscapes dominated by broadleaf trees, scrub and grasslands) and decrease its further resilience to fires (Gil-Tena *et al.*, 2016), with strong impacts on key NCP such as water supply, carbon storage and food production and a possible switch to a different kind of ecosystem. While Mediterranean forests provide various material NCP (Bugalho *et al.*, 2011), scrublands mostly provide non-material or regulating NCP (e.g., pollination, reduction of extreme wildfire hazard, key habitats for biodiversity).

IPLCs have been using fire to promote herbaceous vegetation and useful game or plant species (Pechony & Shindell, 2010; Valladares *et al.*, 2014). Such historical practices and other land-use legacies combined with more recent driving forces, such as land abandonment and fire suppression strategies, have been playing a major role in reshaping the Mediterranean landscapes (Blondel, 2006; Gauquelin *et al.*, 2018; Marlon *et al.*, 2008; Valladares *et al.*, 2014).

Although Mediterranean biodiversity is facing multiple threats and is declining strongly, some driving forces may be turned into conservation opportunities. For instance, large carnivores have been recolonizing abandoned landscapes in many rural areas of the Mediterranean Basin. Although land abandonment and subsequent vegetation encroachment generate conservation concerns, this process is now also considered as an opportunity for rewilding landscapes and exploring new avenues in areas where the socioeconomic context becomes incompatible with the maintenance of traditional agricultural practices (Ceaușu *et al.*, 2015; Navarro & Pereira, 2012).

2.2.7.5 Arctic and mountain tundra

Tundra vegetation, composed of low-growing herbaceous plants, shrubs, mosses, and lichens, grows beyond the cold limit of tree growth. Two types are recognized: mountain tundra at high elevations, and arctic tundra at high latitudes. Arctic tundra is found in Russia, Canada, the U.S., and Greenland but is not present in Scandinavia, Iceland, or the Aleutian Islands (CAFF, 2013; Walker *et al.*, 2005). This distribution corresponds roughly with the distribution of permafrost in soils, while mountain tundra soils have no permafrost. One effect of permafrost is that water from snow and rain is retained in the surface layers of soil; plants grow better in these moist soils than in the drier soils of mountain tundra. Species richness in the tundra is low; for example, the arctic tundra contains only 9% of the world's species of plants and animals.

The low numbers of people who live in the tundra regions have little effect on the native plants and animals. High plant productivity and low predator densities in arctic tundra (Bhatt *et al.*, 2017) support many migrating animals such as reindeer/caribou, muskox, fish, and birdlife including millions of geese. Harvest of these animals supports Indigenous Peoples and recreational hunting in temperate regions. In general, both ecosystems are still functionally intact, though in some areas used for seasonal herding, impacts are notable. Arctic and high mountain tundra are recognized as water towers (Chettri *et al.*, 2012; Viviroli *et al.*, 2007), but they are sensitive to multiple drivers including climate change (Myers-Smith *et al.*, 2015).

There are indications of higher warming in high mountains (Shrestha *et al.*, 1999) resulting in species range shifts (Gottfried *et al.*, 2012; Liang *et al.*, 2018; Pauli *et al.*, 2012; Tape *et al.*, 2016), phenology change (Bjorkman *et al.*, 2015; Tao *et al.*, 2018) and low plant productivity (Bhatt *et al.*, 2017). The arctic region is warming at roughly twice the global average (Pithan & Mauritsen, 2014), resulting in a warmer, wetter, and more variable environment. The permafrost in the high arctic has warmed by more than 0.5°C since 2007–2009 (AMAP, 2017); as a result, microbes release large amounts of carbon gases from the plant debris previously frozen in the soil (Schuur *et al.*, 2008). The carbon stored in the upper few layers of arctic soil is equal to twice the carbon in the world's atmosphere (Tarnocai *et al.*, 2009).

These transformations have profound implications for people, resources, and ecosystems (Arctic Council, 2016). IPLCs in arctic tundra report that they are already significantly challenged by changes to weather and ice conditions as well as by climate-induced shifts in hunting opportunities (e.g., fewer safe boating and hunting days, changing ice melting patterns), the animals they hunt, or the size of the grasslands they use for pastures (Cuerrier *et al.*, 2015; Huntington *et al.*, 2016; Parlee *et al.*, 2014). Mountain IPLCs perceive degrading rangeland conditions because of climate change (e.g., fewer flowers, height of the vegetation, reduced quantity of forage plants, more bare soil on pastures; Hopping *et al.*, 2016; Ingty, 2017), exacerbating alterations in mountain vegetation from high altitude pasturing for millennia (which has lowered the treeline and increased tundra in many mountain ranges; Catalan *et al.*, 2017).

2.2.7.6 Tropical and subtropical savannas and grasslands

Tropical savannas and grasslands cover about one fifth (~33 million km^2) of the global land surface (Beerling & Osborne, 2006; Ramankutty & Foley, 1999; Scholes & Walker, 1993). The ecosystem services they provide sustain the livelihoods of one fifth of the world's people, and they are also home to majority of the world's livestock and much of its charismatic wildlife (Lehmann *et al.*, 2014; Parr *et al.*, 2014; Sankaran *et al.*, 2005; Solbrig, 1996).

Savannas and grasslands are ancient ecosystems (originating 8–10 Mya) that support unique biodiversity (Bond & Parr, 2010; Murphy *et al.*, 2016; Ratnam *et al.*, 2011; Veldman *et al.*, 2015a). The misconception that they are 'derived' from forests through deforestation and other land-use processes and are therefore somewhat "degraded" has resulted in mismanagement of their biodiversity, and conversion to other land uses such as agriculture and tree plantations (Bond & Parr, 2010; Murphy *et al.*, 2016; Parr *et al.*, 2014; Ratnam *et al.*, 2016; Veldman *et al.*, 2015a). It is estimated that ~ 6.7 million km^2 of savanna, grassland and steppe habitats were converted to croplands between 1700 and 1992 (Ramankutty & Foley, 1999), with >80% of grassland and savanna habitats being converted to anthropogenic land uses by 2000 (Ellis *et al.*, 2010; Ellis & Ramankutty, 2008). Currently, the savannas of northern Australia are the least impacted savannas (Murphy *et al.*, 2016) while neotropical savannas are amongst the most threatened (Strassburg *et al.*, 2017), globally. Very little of Asia's savanna and grassland habitats remain (Lambin *et al.*, 2003; Miles *et al.*, 2006; Murphy *et al.*, 2016).

Species richness in tropical savannas and grasslands can be quite high, and in some cases comparable to forests (Murphy *et al.*, 2016), with the Neotropics and Afrotropics especially diverse (Murphy *et al.*, 2016). In forests much of the diversity resides in the tree layer, but grasses and forbs contribute substantially to plant species richness in tropical savannas and grasslands (Bond & Parr, 2010; Murphy *et al.*, 2016; Ratnam *et al.*, 2016; Sankaran, 2009).

Grazing and fire are integral features of savannas and grasslands and essential to their persistence (Bond, 2008; Bond & Parr, 2010; Parr *et al.*, 2014; Ratnam *et al.*, 2011; Sankaran *et al.*, 2004; Scholes & Archer, 1997). Semi-nomadic and transhumant grazing systems seem to better adapt to and cope with unpredictable climates that characterize these ecosystems than settled and paddocked animal husbandry. Local pastoralists use diverse indicators to understand pasture degradation and regeneration, such as adverse changes in woody or shrubby vegetation, or of unpalatable species (Admasu *et al.*, 2010; Angassa & Beyene, 2003; Jandreau & Berkes, 2016; Kimiti *et al.*, 2016; Lykke, 2000). Active fire suppression can alter species composition and lead to establishment of forest tree species at the expense of savanna trees in more mesic areas (Bond, 2008), and litter build up that fuels more intense fires when they do occur (Ratnam *et al.*, 2016; Stott *et al.*, 1990). Invasions by exotic species, both grasses and trees, may have negative impacts on the native flora and fauna, and may also alter the frequency, intensity and spatial extent of fires (Aung & Koike, 2015; D'Antonio & Vitousek, 1992; Hiremath & Sundaram, 2005; Hoffmann *et al.*, 2004; Ratnam *et al.*, 2016; Rossiter *et al.*, 2003).

Carbon schemes such as REDD+ can undermine grasslands by promoting tree planting (Abreu *et al.*, 2017; Bond, 2016; Griffith *et al.*, 2017; Lehmann, 2010; Parr *et al.*, 2014; Ratnam *et al.*, 2016; Strassburg *et al.*, 2017; Veldman *et al.*, 2015b). In this context, it becomes particularly critical to distinguish 'derived' from 'old-growth' grasslands and savannas, to avoid the significant costs of misguided afforestation of the latter.

Climate change will alter the tree-grass balance, in most continents leading to shrub encroachment and woody thickening (Bond, 2008; Bond & Midgley, 2000; Fensham *et al.*, 2005; Good & Caylor, 2011; Sankaran *et al.*, 2005). Savanna responses to different global change drivers are likely to vary both regionally, and across continents (Higgins & Scheiter, 2012; Lehmann *et al.*, 2014), due to varied vegetation-fire-climate linkages.

2.2.7.7 Temperate grasslands

Temperate grasslands comprise steppes, prairies and pampas, as well as some high-altitude veld, forest-steppes and wood-pastures, covering an area of 13 million km^2 (Dixon *et al.*, 2014; White *et al.*, 2000), or 5–10% of the global terrestrial surface. Temperate grasslands have a high biodiversity of mammals and birds, and huge stocks of carbon stored in their soil. Total carbon stocks have been estimated at 450 – 550 Gt C (18–31% of global terrestrial carbon White *et al.*, 2000) with a correspondingly high potential for carbon sequestration. The capacity to store carbon varies greatly between temperate grassland types and debate is ongoing regarding estimating this capacity (Schierhorn *et al.*, 2013; Sommer & de Pauw, 2010; Wiesmeier *et al.*, 2015.

Several global hotspots for vertebrates and vascular plants (Mittermeier *et al.*, 2004) overlap with temperate grasslands. The Eurasian steppes host the largest long-distance ungulate migrations on the planet (Tucker *et al.*, 2018). North American prairies are relatively recently formed which is why despite massive loss of area relatively few species are at risk of extinction (Risser, 1988).

No other biome has experienced the level of degradation and conversion as temperate grasslands (Henwood, 1998; Hoekstra *et al.*, 2005). In the last century ca. 60% have been converted (White *et al.*, 2000), and <10% remain in North America and Europe, with continuing decline (Gauthier & Wiken, 1988; Korotchenko & Peregrym, 2012; Molnár *et al.*, 2012). By contrast, <1% are converted in Mongolia. Important drivers of change in temperate grasslands are habitat conversion, fragmentation by transport infrastructure, and to a lesser extent local overgrazing. Most temperate grassland plants are adapted to grazing, yet excessive grazing or over haying has led to degradation in many

Eurasian grasslands (Wesche *et al.*, 2016) and in parts of South America (Piñeiro *et al.*, 2006). Invasive species are increasingly problematic, particularly in North America and South Africa (Grace *et al.*, 2001; Han & Young, 2016; Morrow *et al.*, 2015). Decreasing productivity of temperate grasslands and changes in composition towards unpalatable species are the most frequently cited trends (Bruegger *et al.*, 2014; Kakinuma *et al.*, 2014). North American grasslands continue to disappear, at rates equivalent to deforestation in the Amazon, due to conversion to cropland and excessive grazing (Ceballos *et al.*, 2010; Wright & Wimberly, 2013). Extremely rapid development threatens the integrity of Mongolia's vast steppe (Batsaikhan *et al.*, 2014).

For traditional pastoral communities, provision of livestock forage, dung as a fuel and the open landscape are the key NCP provided by temperate grasslands. Conversion to agriculture has slowed down and, in some regions reversed (e.g., Eurasian grasslands), with large-scale farm abandonment in e.g., Russia and Kazakhstan (Chen *et al.*, 2013; Jírová *et al.*, 2012). In China some restoration has commenced (Ren *et al.*, 2016). Shifts to market economies have reduced grazing pressure of livestock in several regions, including Kazakhstan and western Russia (Kühling *et al.*, 2016), and Patagonia (Coronato *et al.*, 2016). Where traditional mobile pastoral practices persist, such as in Mongolia, rangelands are still relatively intact pointing to the importance of ILK and mobility for sustainable use of highly variable rangelands (Bilegsaikhan *et al.*, 2017).

Levels of formal protection of temperate grasslands are low, at about 3.4 – 5.0% of global area (Henwood, 2012), lower than in other major terrestrial biomes. Protection is particularly low (≤ 2%) in South American pampas and the velds of Southern Africa and Australia (Peart, 2008).

2.2.7.8 Deserts and xeric shrub lands

This unit comprises large expanses of arid and hyper-arid lands in tropical and subtropical latitudes characterized by sparse often discontinuous vegetation and large expanses of bare soil. Deserts cover a total of over 33.7 million km^2, representing almost 25 per cent of the terrestrial surface of the planet (UNEP, 2006). Herbivory by large and medium-sized mammals that have evolved to these dry and sparse vegetation conditions is a distinctive feature of these habitats.

Deserts and xeric habitats are characterized by severe shortage of water and are classified as arid and hyper-arid with a precipitation to potential evapotranspiration (P/PET) ratio of 0.05 – 0.20 and < 0.05 (Sorensen, 2007). Deserts may be hot (ground temperatures up to 80°C) or cold, mainly dependent on altitude. Both deserts and xeric shrub lands can have a dense herbaceous/grassy vegetation after the rains for very short periods of the year. The desert biome holds on average an abundance of original species of 68%, highly adaptive to severe climate conditions (UNEP, 2006).

The deserts of the world occur in six biogeographical realms (UNEP, 2006), with varying degrees of anthropogenic influence: **Afrotropic deserts** south of the Sahara in Africa and in the southern fringe of the Arabian Peninsula (2.7 million km^2, mean population density of 21 p/km^2 and a relatively high human footprint; **Australasian deserts** in the Australian heartland (3.6 million km^2, less than 1 person per km^2, and the lowest human footprint); **Indo-Malay deserts**, south of the Himalayas (0.26 million km^2, mean population density of 151 p/km^2, the most intense human use); **Nearctic deserts** in North America (1.7 million km^2, high population density of 44 p/km^2 due to urbanization, and the second highest human footprint); **Neotropic deserts** in South America (1.1 million km^2, a population density of 18 p/km^2 and a lower human footprint than in North America); and **Palearctic deserts** in Eurasia north of the Himalayas and in north Africa including the Sahara (63% of all deserts, covering 16 million km^2; a density of 16 p/km^2, and the second lowest human footprint on the planet, possibly because of inaccessibility and extreme aridity. The flat Sahara and Arab deserts contrast with the mountain deserts of Central Asia.

Deserts and their fringes are currently home to some 500 million people, about 8% of the global population. Traditionally deserts support hunter-gatherers, pastoralists and farmers (in oases and along rivers). Poverty affects many people living in deserts (UNEP, 2006). However, contrary to common belief, deserts are not a final stage of desertification but are natural ecosystems, providing many life-supporting services to mankind.

The main drivers of degradation are urbanization, tourism, intensive agriculture, mining, military operations and climate change. Biodiversity decline in deserts is expected to reach 58% of original species in 2050. Desert wilderness areas are expected to decline from 59% of total desert area in 2005 to 31% in 2050 (UNEP, 2006).

2.2.7.9 Wetlands

Wetlands are permanent or temporary, freshwater, brackish or marine areas, where water either covers the soil or is at or near its surface, either year-round or seasonally. They include floodplains, bogs, swamps, marshes, estuaries, deltas, peatlands, potholes, vernal pools, fens and other types, depending on geography, soil, and plant life. Their global extent remains uncertain (Davidson *et al.*, 2018), but inland wetlands are estimated at 12.1 million km^2, or 6% of the world's land surface (Ramsar, 2018). Wetlands contain about 12% of the global carbon pool, highest in peatlands

(Ferrati *et al.*, 2005; Joosten *et al.*, 2016; Ramsar, 2018). Though valuation of NCP is often problematic, wetlands are estimated to contribute 21.5–30.0% of the value of global NCP (Kingsford *et al.*, 2016). Estuaries support millions of people worldwide (Halpern *et al.*, 2012), contributing food, freshwater and protection from erosion, natural hazards and pollution (Costanza *et al.*, 2014; McCartney *et al.*, 2015; Millenium Ecosystem Assessment, 2005; Russi *et al.*, 2013). They are also often culturally important to IPLCs, often in relation to intangible (e.g., sacred) values (Pyke *et al.*, 2018; Ramsar, 2018; Verschuuren, 2005).

Natural wetlands are declining rapidly: by 0.82–1.21% per year (Davidson *et al.*, 2018; Dixon *et al.*, 2016); by 31% between 1970 and 2008 in areas studied (Dixon *et al.*, 2016), and by 87% between 1700 and 2000 (Davidson, 2014). Historical losses were mostly inland (Davidson, 2014), whereas current declines are predominantly coastal (Dixon *et al.*, 2016). Conversely, human-altered wetlands – which make up about 12% of the global total – are increasing, especially in southern Asia and Africa, mainly through conversion of natural wetlands into paddy fields, which now cover 1.3 million km^2 (Davidson, 2014; Junk *et al.*, 2013; Ramsar, 2018). Rice paddies deliver multiple NCP, including pest control, soil fertility and fish production (McCartney *et al.*, 2015). Globally, IPLCs have many traditional wetland management systems. For example, the most biodiverse Norwegian swamp woodlands are managed by traditional grazing and hay mowing (Natlandsmyr & Hjelle, 2016).

Changes in the water inflows and abstraction, and structural modifications (e.g., drainage and conversion) all directly drive the loss of inland wetlands (Ramsar, 2018). Indirect drivers include overfishing, intensive wood harvesting (e.g., in wetland forests), peat extraction, and sand and gravel extraction for construction (Ramsar, 2018). The two largest peatlands in the world (northeastern Peru and Republic of Congo) are threatened by commercial agriculture, transport infrastructure, and oil palm and timber concessions (Pearce, 2017). In estuaries, increased fluvial sedimentation due to unsustainable land-use or climate change can significantly reduce fish and benthic diversity (Nicolas *et al.*, 2010).

Freshwater marshes support disproportionately high biodiversity for their size (Kingsford *et al.*, 2016), and several wetland types found in a mosaic with forests and mires, are important for biodiversity but poorly studied (Gupta *et al.*, 2006; Struebig & Galdikas, 2006). Wetland biodiversity is declining globally, with 25% of assessed species threatened with extinction (Ramsar, 2018); 45% of mammals and 33% of birds in the South Asian Tropical Peat Swamp Forests are Near-Threatened, Vulnerable or Endangered (Posa *et al.*, 2011). The fraction of wetland area under formal protection varies widely depending on definitions used, ranging from 11.3% to 20.4% (Reis *et al.*, 2017).

Climate change is already a major driver of wetland structural change and influences water volumes, flows, temperature, invasive species, nutrient balance and fire regimes (Erwin, 2008; Finlayson, 2018). The importance of wetlands for carbon sequestration is increasingly recognized, and their loss can trigger further carbon release; annual emissions of carbon due to peat oxidation in Indonesia are equivalent to emissions from fossil fuel burning in Canada (Pearce, 2017).

Positive actions on wetlands are expanding, particularly in the USA and Europe, where wetland restoration efforts are increasing (Reis *et al.*, 2017), including monitoring of birds (Heldbjerg *et al.*, 2015) and protection of peatlands. Numerous benefits from restoration have been documented (e.g., Erwin, 2008; Reis *et al.*, 2017); the incorporation of diverse perspectives, including indigenous and local knowledge, in wetland management is crucial for effective restoration (Russi *et al.*, 2013). However, landward migration of estuaries will depend on the availability of habitats and coastal development.

2.2.7.10 Urban/semi-urban

Urban and semi-urban areas cover approximately 88 Mha, less than 0.6% of the world's land surface (Klein Goldewijk *et al.*, 2017), on which 54% of the world's population lives (World Bank, 2017). Urban expansion now is more rapid, more extensive and fundamentally different from how urban areas grew in the past (Seto *et al.*, 2010). Europe and North America dominated urban growth from 1750–1950, but in 1950–2030, the total population of African and Asian cities is predicted to grow more than tenfold – from 309 million to 3.9 billion (Ramalho & Hobbs, 2012).

Urban areas are heterogeneous in relation to biodiversity and NCP, through a variety of natural, altered and novel habitats that support varied animal and invertebrate species. Fertile soils in urban areas enable urban residents to grow food (~15–20% of the world's food; Armar-Klemesu, 2000), and green spaces provide recreational, cultural and health NCP (Gómez-Baggethun *et al.*, 2013).

Urban areas are usually rich in non-native species, whether naturalized or maintained in gardens, and extension occurs usually into agricultural more than natural land. Vegetation in urban areas often has enhanced growth relative to matched rural settings (Zhao *et al.*, 2016). Land conversion is greatly reducing the extent of green space within many of the world's cities (Bagan & Yamagata, 2014). At low levels of urban development, local species numbers may increase due to habitat heterogeneity (McKinney, 2002). Non-native species may predominate in larger than smaller settlements (as many as 50% of species in a city centre can be non-native) and accumulate over time (Muller *et al.*, 2013). Biotic homogenization increases along rural-urban gradients with city centres featuring "global homogenizers" – weeds, pests and commensals. Disease organisms and parasites can become abundant in urban systems, through the large reservoirs of animal (e.g., rats, bats, birds, foxes – (Hassell *et al.*, 2017)) and human hosts.

Attribution of trends to drivers of varied species densities can be difficult because of legacies of previous land use, transient dynamics, and few studies consider all the relevant drivers (Ramalho & Hobbs, 2012). The main direct driver is replacement of vegetation by impervious surfaces. In the US, domestic cats (mostly feral) kill 1.3–4.0 billion birds and 6.3–22.3 billion mammals per year (Loss *et al.*, 2013). Pollution in urban areas is omnipresent, with nutrients and trace metal elements coming from residential, commercial business and industrial complexes (Khatri & Tyagi, 2015). Waste treatment within or close to urban areas is a big driver of ecosystem change and threat to freshwater and animal species.

Phenotypic evolution is accelerated in urban landscapes compared to natural or agricultural ones (Alberti *et al.*, 2017), as species adapt to novel and rapidly changing conditions. Urban ecosystems can provide insights into some aspects of climate change, cities tend to have higher temperatures because of the heat island effect, higher CO_2 levels and higher nitrogen deposition (Zhao *et al.*, 2016).

Cities and municipalities have embarked on restoration of ecosystems, such as species diversity enhancement, or conversion of sewerage treatment plants to natural systems of waste treatment, filtering and purification (Allison & Murphy, 2017). In some city-regions, tree-planting as a restoration drive is combined with social interventions to create economic opportunities and address poverty (Mugwedi *et al.*, 2017).

2.2.7.11 Cultivated areas

Cultivated systems are areas in which at least 30% of the landscape is in farmland or confined livestock production and managed for food/feed production. Globally 80% of the 1.6 billion ha of cultivated lands are rainfed; 20% occur in marginally suitable areas (FAO, 2011b). Further, 43% of cultivated lands are considered as agroforestry systems with more than 10% tree cover (Zomer *et al.*, 2016). These cultivated systems are vital for sustaining food production and meeting the food and nutritional needs of growing human populations projected to exceed 9 billion people by 2050 (FAO, 2017). The world's cultivated area has grown by 12% over the last 50 years, trebling the agricultural production (FAO, 2011b) to meet food demands.

Cultivated systems can themselves be degraded through human actions, and agriculture has the potential to have massive irreversible environmental impacts (Tilman *et al.*, 2001). The combined impact of land degradation, desertification and drought affect more than 1.5 billion people in 110 countries, 90% of whom live in low income areas (FAO, 2011b). Excessive use of fertilizers and pesticides have exacerbated land and soil degradation and erosion, although appropriate soil conservation practices that reduce erosion, such as minimum tillage, are increasingly being adopted by farmers (Derpsch *et al.*, 2010). There exist also many good examples of positive interactions between agriculture and biodiversity in agroforestry systems, species-rich meadows and other managed cultivated systems with biodiversity objectives in mind.

Land conversion of natural ecosystems to agriculture continues to be a major issue. Between 2000 and 2012 global oil palm planting area has expanded from 10 to 17 million ha (Pirker *et al.*, 2016). A new paradigm, sustainable intensification (SI), is now emerging to grow more food more intensively, based on the need for increasing productivity while increasing environmental sustainability (Biodiversity International, 2017; FAO, 2011a; Garnett *et al.*, 2013).

Globally livestock production is the largest user of agricultural land and therefore also leaves a significant imprint on the environment (FAO, 2015b). Data suggest that there are large differences between production systems and type of livestock and demonstrate the importance of grasslands as a global resource (Herrero *et al.*, 2013).

Key drivers negatively affecting cultivated areas include **climate change**: IPCC (2014) predicts that climate change will reduce agricultural production by 2% every decade while demand will increase by 14% every decade until 2050. Up to 40% of the world's land surface will develop novel climates, often with new pest and weed complexes (Lobell & Field, 2007). **Pollution**: there is evidence that the use of toxic agrochemicals and systemic pesticides, such as neonicotinoids, in cultivated systems is affecting non-agricultural lands and wild biodiversity including pollinators and other beneficial organisms (Dudley *et al.*, 2017). **Invasive alien species**: transboundary pests and diseases are resulting in total crop failure and affecting the productivity of cultivated systems. Globally, annual crop losses to plant pests are estimated to be between 20 to 40 per cent of production (FAO, 2017). These drivers will negatively impact the capacity of cultivated systems to continue to provide food and feed and to ensure the sustainability of food and nutritional security of human populations in decades to come.

2.2.7.12 Cryosphere

The Cryosphere is comprised of all locations on Earth with frozen water, including the Arctic, Antarctic, and glaciated mountain ranges within the polar regions. It stores about 70% of the world's freshwater as ice (Gleick, 1996), helps to radiate energy back out to space with its high-albedo surfaces, and is home to many extremophiles (Thomas & Dieckmann, 2002). This region contains fewer, larger, and more-complex organisms than temperate and tropical ecosystems.

The Cryosphere contains many unique ecosystems: **Ice sheets, glaciers, and ice shelves** contain all of the terrestrial, and terrestrially connected, ice on Earth. This land ice provides fresh water into adjacent ecosystems during melting events. The ice is home to extreme microbes living within thin water veins between ice grains. **Sea ice** covers portions of the Arctic and Southern Oceans, varies in extent seasonally, and provides shelter and hunting opportunities for many polar animals including polar bears, seals, penguins, and orcas. **Extreme deserts**, such as the Antarctic Dry Valleys, provide insight into the limits of life on Earth, and the types of microbial ecosystems that may be on other planets (Convey, 2006). **Sub-glacial lakes** found under ice sheets, such as Lake Vostok, Antarctica, are isolated systems where organisms have evolved independently for millions of years.

Climate change is having the greatest impacts on Arctic ecosystems, where warming has occurred at more than twice the global average during the past 50 years (Pithan & Mauritsen, 2014). Arctic land ice volume (Gardner *et al.*, 2013), supporting ice shelves of the East and West Antarctic ice sheet (Hillenbrand *et al.*, 2017; Pritchard *et al.*, 2012), snow cover duration and extent (Derksen & Brown, 2012), and sea ice thickness and extent are declining (Lindsay & Schweiger, 2015). The rapid warming is causing global sea level rise (Nerem *et al.*, 2018), poleward and upward advancement of the treeline (Harsch *et al.*, 2009), altering ranges of Arctic species including polar bears (Rode *et al.*, 2012) and caribou (Vors & Boyce, 2009), altering animal diets (Rode *et al.*, 2015), shifting predator-prey relationships due to phenological mismatches (Gilg *et al.*, 2009), changing migration patterns of many species including anadromous fish (Mundy & Evenson, 2011), and desiccating terrestrial freshwater systems (Smol & Douglas, 2007). In the Southern Hemisphere, the strongest rates of warming are occurring in the West Antarctic Peninsula causing growth rates and microbial activity to rapidly increase (Royles *et al.*, 2013). The Southern Ocean also continues to warm and freshen from increased precipitation and ice melt (Swart *et al.*, 2018).

Sea level rise and severe storms have destabilized Arctic infrastructure, disrupting the physical, social, and cultural well-being of IPLCs (Cochran *et al.*, 2013), and in some cases, forcing relocation (e.g., Alaska, (Maldonado *et al.*, 2014)). ILK has been used in conjunction with Western science to further study the impact of climate change on Polar Regions (Pearce *et al.*, 2015). Trends observed by IPLCs relate mostly to population trends such as reduced number of seals and increased population size of bears (Wong & Murphy, 2016).

There are increased economic opportunities due to the increased number of ice-free days within the Northern Sea Route (Russia) and Northwest Passage (Canada), which will increase land- and freshwater-based transportation networks in the Arctic (Khon *et al.*, 2010), bringing increased risk of ecological damage. The Arctic Council and its circumpolar indigenous participant groups work to support research and legislation aimed at resolving issues surrounding sustainable development and environmental protection, through sharing of knowledge.

2.2.7.13 Aquaculture

Aquaculture converts terrestrial, freshwater or marine areas to farming of aquatic organisms, driven by depletion and stagnation of wild fisheries and rising demand and recognition of nutritional and sustainability benefits of aquaculture (Mungkung *et al.*, 2014; Pelletier *et al.*, 2011; Troell *et al.*, 2014a; Waite *et al.*, 2014). Estimates of global area of biomes converted to aquaculture does not exist – only sporadic national statistics (Ottinger *et al.*, 2016). Freshwater fish from ponds makes up 60% of global aquaculture production, marine mussels and oysters 21%, shrimps and other crustacean from ponds 10% and marine finfish (mainly cages) 8.5% (FAO, 2018). Farmed seaweed production reached 30 million tons in 2016 (FAO, 2018). China, India and Southeast Asian countries represent 80% of global aquaculture production (FAO, 2018), followed by Bangladesh, Egypt and Norway.

Aquaculture production is projected to grow 15–37 per cent by 2030 (FAO, 2018; Kobayashi *et al.*, 2015; World Bank, 2013), led by currently dominant species and countries (FAO, 2018; Hall *et al.*, 2011). Expansion faces challenges related to environmental impacts and competition for resources, e.g., feed, freshwater and energy (Bostock *et al.*, 2010; FAO, 2018; Gephart *et al.*, 2017; Pahlow *et al.*, 2015; Troell *et al.*, 2014b). Access to space will be an issue for land and coastal farming but not for offshore ocean aquaculture (Klinger *et al.*, 2017; Oyinlola *et al.*, 2018; Troell *et al.*, 2014a).

Aquaculture is the fastest growing food sector contributing 80 million tons (53 per cent) to global food fish production (FAO, 2018). Although 600 freshwater and marine species, across multiple trophic levels and culture techniques, are farmed worldwide, about 20 species comprise 84 per cent of total aquatic animal production (FAO, 2018). The value of mariculture products reached 65 billion USD in 2013, or 43 per cent of global aquaculture (Oyinlola *et al.*, 2018).

Sustainability of culture species and systems varies widely (Gephart *et al.*, 2017; Henriksson *et al.*, 2015; Klinger & Naylor, 2012; Troell *et al.*, 2014a). Today, 70% of total animal aquaculture production relies on supplemental feed (FAO,

2018) derived from a wide variety of food quality and human inedible sources, with important repercussions on the resilience of the world's food systems (Froehlich *et al.*, 2017; Naylor *et al.*, 2009; Tacon *et al.*, 2011; Tacon & Metian, 2015; Troell *et al.*, 2014a, 2014b).

Climate change and global change, including unfavorable temperature regimes, hypoxia, sea level rise, ocean acidification, floods, diseases, parasites and harmful algal blooms and freshwater shortage (Barange *et al.*, 2018; Myers *et al.*, 2017) challenge aquaculture production. Antimicrobial use in aquaculture is also a cause of concern in relation to antimicrobial resistance (AMR) (Han *et al.*, 2017; Henriksson *et al.*, 2018; Rico *et al.*, 2012).

Aquaculture can contribute to the global sustainability goals by providing incomes and supporting food security, especially in low and medium income countries. (Béné *et al.*, 2016; FAO, 2017). Farmed fish and shellfish are high in protein and rich in micronutrients, and employment is created throughout the aquaculture value chains (Béné *et al.*, 2016; Beveridge *et al.*, 2013; Bostock *et al.*, 2010). However, corporate and community aquaculture have very different benefit sharing outcomes, particular for the poor. This requires appropriate policy development in producer countries.

2.2.7.14 Inland waters

Inland waters are permanent water bodies, including all types of lakes independent of salinity and depth, rivers, streams, ponds, water courses, cave waters). Declines in biodiversity of fresh waters are greater than those in the most affected terrestrial ecosystems (Dudgeon, 2005; Sala *et al.*, 2000). In Europe, 59% of freshwater mollusks, 40% of freshwater fishes and 23% of amphibians are threatened with extinction, due to chemical stressors, climate change and UVB radiation (IUCN, 2017). Freshwater species populations suffered an 81% decline (WWF, 2016).

Total diversity of fresh waters is far from being completely studied (Cazzolla Gatti, 2016). 115–188 new amphibian species were described annually between 2004–2016 (Amphibia Web, 2017). Since 1976 around 305 fish species have been described annually (Reid *et al.*, 2013). Lake Ohrid is a major European biodiversity hotspot, characterized by its narrow endemism, however this is under threat from a wide range of anthropogenic pressures (Kostoski *et al.*, 2010).

Flow modification is a particular risk for river ecosystems degradation. Dams change turbulent flowing waters to still, creating unfavourable conditions for specialist and endemic species and altering assemblages of taxonomic groups (Liermann *et al.*, 2012). Retention of water in dams is as high as five times the volume of all the world´s rivers (Nilsson & Berggren, 2000). 172 out of the 292 large river systems are affected by dams, with Europe having the smallest number of completely unfragmented river systems (EEA, 2015; Nilsson *et al.*, 2005). The Mekong, Congo and Amazon are the most biodiverse river basins on Earth affected by dam construction (Winemiller *et al.*, 2016).

Global environmental changes such as nitrogen deposition, climate change, shifts in precipitation and runoff patterns (Galloway *et al.*, 2004) affect inland waters, and are superimposed upon other localized threats (Dudgeon, 2005).

Biodiversity losses can affect water quality, e.g., by loss of species that remove excessive nutrients (Cardinale, 2011). Populations of different important fish species declined significantly, while introduced species transform the original fish communities (Aigo & Ladio, 2016; Gray *et al.*, 2017).

2.2.7.15 Shelf systems

Shelf systems extend from the shoreline to 200m deep, comprising 8% of the earth's surface (Kaiser *et al.*, 2011) and contribute 90% to the world's marine primary production (Longhurst *et al.*, 1995). They are influenced by adjacent terrestrial systems and watersheds; urban, aquaculture and intensively used coastal areas; and in polar regions, the cryosphere. This makes shelf ecosystems among the most vulnerable to cumulative and intensifying local to global impacts.

Shelf systems comprise several subunits: **mangrove forests** and **seagrass beds** are dominated by flowering plants adapted to saltwater. Both sequester more carbon than tropical rainforests. **Coral reefs** flourish in shallow tropical seas due to symbiosis between hard corals and intracellular dinoflagellates. Other **biogenic reef** habitats are created by e.g., tubeworms, bivalves, and sponges. The intertidal zone, comprising **rocky and sandy shores**, is controlled by physical extremes and aerial exposure in upper levels, while ecological interactions dominate at lower levels. **Macroalgal** habitats become more dominant at higher latitudes, with giant kelp reaching heights of 40 m. Submerged habitats on the shelf include rocky, cobble, sand and muddy bottoms, which determine the biological communities they support. **Deep coastal inlets and fjords** support concentrated diversity hotspots. **Polar shelves** with poorly sorted sediments especially in the Southern Ocean support unusually high biomass of heterotrophs (Gutt *et al.*, 2013). **Coastal pelagic** areas include highly productive waters where plankton are the primary and secondary producers and sustain rich fisheries yield, such as polar seas, the North Sea, Sea of Okhotsk and East China Sea.

Shallow shelf ecosystems have supported human uses for tens of thousands of years as a result of their accessibility and high productivity, for fishing, natural products, tourism and coastal development. Cumulative impacts are evident (Selig *et al.*, 2014). Global cover of mangroves (134,000 km^2) has declined 37.8% (Thomas *et al.*, 2017). Shallow coral reefs have shown long-term decline (Pandolfi *et al.*, 2003) and are losing live coral cover at a rate of 4% per decade (Section 2.2.5.2.1); severe global bleaching events are increasing in frequency and intensity because of rising temperatures (Hughes *et al.*, 2018). Conditions currently unsuitable for persistence of shallow coral reefs globally are predicted to occur within the next 10–50 years at almost all reef locations globally (Beyer *et al.*, 2018; van Hooidonk *et al.*, 2016), and >33% of coral species are listed as Threatened (Carpenter *et al.*, 2008). The reef-associated fish species Living Planet Index (LPI) declined 34 per cent between 1979 and 2010 (WWF, 2015).

Drivers of shelf ecosystem decline include fishing, eutrophication, solid and liquid waste, habitat fragmentation, underwater noise from shipping and invasive species. Indirect effects of land-use change are mediated through freshwater runoff from land and in rivers. Climate change is increasingly pervasive in shelf systems (Hoegh-Guldberg *et al.*, 2014), through increasing temperature, acidification, deoxygenation and intensifying storms. They fundamentally affect species' life histories, as well as the physical structure of the coastline and shelf.

Shelf ecosystems are of great significance to IPLCs. Many coastal cultures have detailed histories and mythologies related to them (Lee, 2014), as well as centuries and even millennia-old practices and customs demonstrating intimate adaptation (Johannes, 1981). However, the commercial overexploitation and decline of many shelf ecosystems contributes to the loss of these traditions. Both IPLCs and scientists document the decline in abundance of fish species (e.g., sawfish species in Brazil) and weight of fish (e.g., goliath grouper) (Giglio *et al.*, 2015; Reis-Filho *et al.*, 2016).

Shelf ecosystems are an increasing focus for management and protection. Marine Protected Areas and sectoral tools (e.g., in fisheries, shipping, etc.) are now being integrated into novel approaches including Integrated Coastal Zone Management (Clark, 1992) and Marine Spatial Planning (Ehler & Douvere, 2009). Direct and spatially explicit conservation and protection measures are generally local, though increasingly applied at scale as countries approach 10% targets for marine area management. Improving the effectiveness of management is recognized to be equally important as area, to assure benefits accrue to users (Cinner *et al.*, 2016; Edgar *et al.*, 2014).

2.2.7.16 Surface open ocean

The surface open ocean is the shallower light-flooded layer offshore of the 200-m depth contour **(Figure 2.2.26)**. It covers 65% of the earth's surface (Kaiser *et al.*, 2011), converts regionally high amounts of carbon and nutrients to biomass, and remineralizes more than 95% of this organic matter (Ducklow *et al.*, 2001). The surface open ocean and shelf ecosystems produce 50% of atmospheric oxygen (Field *et al.*, 1998) and sequester anthropogenic CO_2, which is essentially important for almost all life on Earth. This function is expected to weaken with increasing climate change. Biological processes in the surface open ocean are driven by sunlight, nutrient availability, and water mass stratification. The unit exchanges with the deep sea through downward flux of organic matter, upwelling of nutrients and vertical migration of organisms.

The surface open ocean comprises different ecosystems: **Central Oceanic Gyres** contribute to the global dispersal of heat, nutrients and organisms. They include oligotrophic 'deserts' and highly productive areas (Westberry *et al.*, 2008). **High-Nutrient Low-Chlorophyll Systems** occur in the Southern Ocean, the subarctic and equatorial Pacific Ocean, where phytoplankton growth is not limited by macronutrients (Pitchford & Brindley, 1999). **Cold and Ice-Covered Polar Seas** are driven by high seasonality and low temperatures. Their productivity supports krill (Atkinson *et al.*, 2008), which feeds penguins, seals, and whales that migrate across the oceans. **Upwelling Systems** allow high fishing yields based on high primary production (Kämpf & Chapman, 2016). **Oxygen Minimum Zones** are caused by excess carbon decomposed by bacteria with anoxic metabolism (Karstensen *et al.*, 2008; Levin, 2003).

Due to its size, the surface open ocean is still poorly characterized in spite of centuries of ocean voyages and expeditions. Its approximately 7000 species are less than in some coastal systems and the deep sea (Bucklin *et al.*, 2010). Hotspots in species richness are for example in the marginal seas of Southeast Asia and polar regions.

The surface open ocean is vulnerable to threats, including from fisheries, pollution including waste, shipping, and noise. Environmental changes have been documented in ocean circulation and chemistry, thermal stratification, composition and growth of phytoplankton (Boyce & Worm, 2015; Sarmiento *et al.*, 2004), biogeochemical cycling (Hoegh-Guldberg & Bruno, 2010; O'Brien *et al.*, 2017), and distribution of ecologically key species (e.g., Beaugrand, 2009) with effects on food webs (Knapp *et al.*, 2017; Smith *et al.*, 2008). Fishing has altered trophic relationships (Pauly *et al.*, 1998; Richardson *et al.*, 2009), the number of overexploited fish stocks, e.g., of tuna and billfish has increased over the past decades resulting in regionally declined fishing yields by 50% (Sherman & Hempel, 2009;

Worm *et al.*, 2005). Waste accumulation is documented though poorly known (Bergmann *et al.*, 2015). Extinction risk for open ocean species has been assessed for seabirds, tuna and sharks (Brooks *et al.*, 2016).

The ocean surface is sensitive to climate change**,** experiencing a globally averaged 0.44°C warming between 1971 and 2010 (IPCC, 2014). Ocean acidification affects not only key calcifying pelagic organisms, such as pteropods and coccolithophorids, it potentially changes the physiology of all species (e.g., Manno *et al.*, 2007).

Interactions of IPLCs with the surface open ocean includes the historic navigation of Micronesian and Polynesian seafarers (Lee, 2014) and is found in notes of captains of fishing vessels, whalers, and explorers (Holm *et al.*, 2010; Rodrigues *et al.*, 2016).

Protective management of surface open ocean systems is increasing as they become less remote with modern technology, trade and extension of governance regimes. In spite of increased pressure, the number of sustainably managed fish stocks has increased (FAO, 2014b; Marine Stewardship Council, 2016). Targeted species such as Antarctic fur seals and humpback whales are recovering (Zerbini *et al.*, 2010) and strategies to reduce by-catch by longlines and driftnets of e.g., turtles, albatrosses, and dolphins are being developed (Hall *et al.*, 2000; Kennelly, 2007). The area of ocean under protection is expanding with accelerating designation of Marine Protected Areas and development of legally binding instruments for governing the High Seas (Wright *et al.*, 2015a).

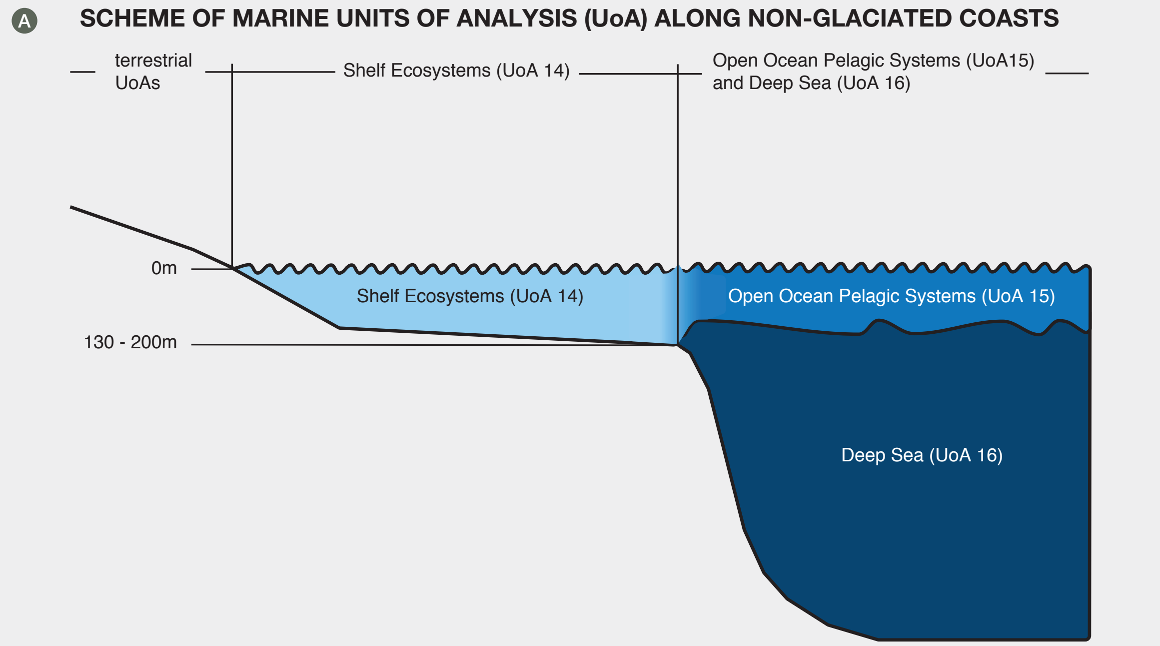
2.2.7.17 Deep sea

The deep sea is the largest and most three-dimensional habitat on Earth. It comprises the dark waters below the euphotic zone (200 m, **Figure 2.2.25**), where biological processes remineralise nutrients and sequester carbon, including of anthropogenic origin, as well as other ecologically important elements. Almost all life in the deep sea depends on climate-sensitive biological processes in the surface layer (Smith *et al.*, 2008) and in the sea ice (unit 11). Through the globally connected current system damage to deep sea ecosystems, especially by pollution, affects natural resources directly used by man.

The deep sea comprises a number of components: the **Slope and Rise of Continents and Islands** from 200 to 4000 m depth, are characterized by characterizedverse environmental gradients and peak benthic species richness between 1500 and 3000 m (Ramirez-Llodra *et al.*, 2010). The **Abyssal Plain** from 4000 to 6000 m covers the largest area (more than 50% of the Earth's surface), where due to limited food availability metabolic rates and biomass are low (Woolley *et al.*, 2016). Faunistic depth gradients are superimposed by a decrease in species richness from the equator to the poles (Ormond *et al.*, 1997). One of the most speciose bottom-dwelling animal groups are nematodes (e.g., Danovaro *et al.*, 2010), whilst bacteria perform highest biological turnover rates. The **Mid-Ocean Ridges** are created by seafloor spreading, with peaks between 5000 and 2500 m above the abyssal plains. Their complex topography and variable sediments shape seabed and pelagic assemblages (Vecchione *et al.*, 2010). **Vents and Seeps** provide energy in the form of methane and sulphides, driving chemosynthetic food webs based on specialized microorganisms (Baker *et al.*, 2010); similar communities develop on whale falls. Some vents provide clues to the deep biosphere living within deep sediments and the ocean crust (Schippers, 2016). **Seamounts** rise more than 1000 m above the surrounding seabed (Clark *et al.*, 2009), where upwelling of nutrients increases biological productivity. Their sessile benthic filter feeding biota is highly endemic (Richer de Forges *et al.*, 2000). Seamount productivity supports abundant fishes, sharks, turtles, marine mammals and seabirds. **Deep-Water Coral Reefs** create a three-dimensional habitat for a rich associated fauna without light-enhanced growth (Freiwald *et al.*, 2004). **Deep-Sea Trenches** occur between 6000 and 11,000 m depth, with a fauna low in abundance and biomass. Life in the **Deep Aphotic Pelagic Zones**, including the meso-pelagic twilight zone (200–1000m; Sutton *et al.*, 2017), and the bathyal, abyssal, and hadal zones (1000–11,000 m) mostly depends on organic matter falling from the light-flooded surface water layers. It comprises gelatinous invertebrates and midwater fish adapted to a stable environment (Ramirez-Llodra *et al.*, 2010).

The low abundance of organisms and low scientific sampling in the deep sea and an assumed high proportion of range-restricted species make species numbers hard to assess, but it is thought rival other global biodiversity hotspots (Knowlton *et al.*, 2010).

Anthropogenic damage in the deep sea is less than in shallow waters and on land but is increasing rapidly. A severe impact is bottom trawling (Clark *et al.*, 2015) on fish (e.g., grenadiers and orange roughy), resulting in rapid decline of yields of slow growing species after a short phase of overfishing and damage to unique benthic habitats, especially on seamounts. Deep-sea mining is expected to be a major threat in the near future (Jones *et al.*, 2017). Long-term effects of dumped waste, especially radioactive material and plastics is still largely unknown (Bergmann *et al.*, 2015). Due to adaptation to a stable environment most deep sea organisms are sensitive to environmental changes, especially to climate-induced shifts in energy supply, alteration of biogeochemical cycles including ocean acidification and prey-predator interactions.



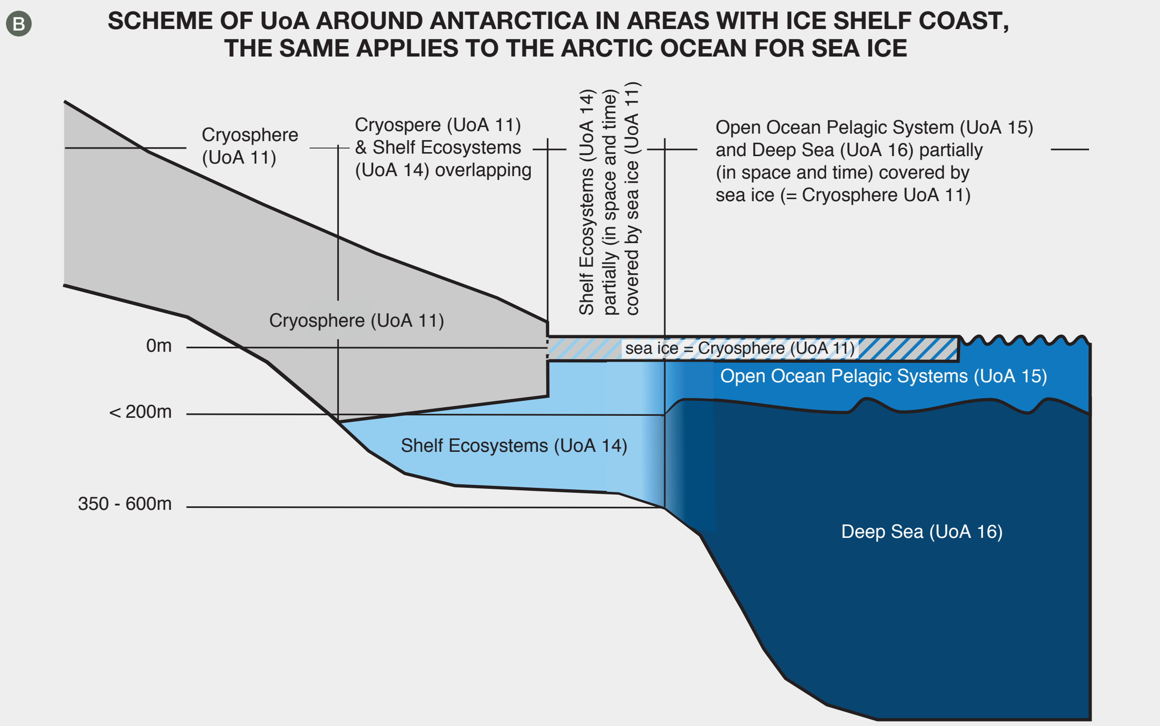


Figure 2 2 25 **A The ocean units (14, 15 and 16) are distinguished across biological and environmental gradients rather than by discrete differences in water masses, nutrient supply, sediment characteristics, and species assemblages. The boundary between units 15 and 16 is usually denoted by the compensation depth, above which primary production happens, and set by convention at approximately 200 m depth, but this can vary over space. B the relationship between shelf (unit 14) and open ocean (unit 15) units and the crysophere (unit 11) is complex, as ice layers over water and may be land-fast or free-floating. Further, the boundary between units 14 and 15/16 is at the 200-m depth contour around most continental shelves, down to 500 m in Antarctica.**

Historic indigenous knowledge on deep sea organisms is common to many ancient seafaring cultures, in the form of tales of mythical bizarre creatures from an unknown world (Ellis, 2006). Conservation of deep sea habitats is still rudimentary and sectoral, but concepts for ecosystem management and Marine Protected Areas to reduce the impact of bottom trawling (Wright *et al.*, 2015b) and deep sea mining (Wedding *et al.*, 2013) exist.

2.2.7.18 Coastal areas intensively and multiply used by humans

The coastal area includes the coastal waters, the seabed, adjacent land and nested waterbodies (including freshwater). Coastal areas extend along more than 1.6 million km of coastline in a total of 123 countries (UNEP, 2006). At present a third of the world's population is living in the coastal zone and almost 40% of the world lives within 100 km of the coast (Agardy *et al.*, 2005).

Coastal areas are experiencing an intensification of multiple uses, due to human population growth, migration from inland regions, tourism and economic growth. Coastal land is used for human settlement, agriculture, trade, industry and amenities. The coastal sea is intensively used for transport, fishing, dumping, mining, and more. Furthermore, coastal areas are the "sink" for the continents; they receive and concentrate pollutants and other negative consequences of anthropogenic activities. Carbon cycling in the coastal sea that connects terrestrial with open ocean systems plays an important role in the global carbon cycles and budgets (Regnier *et al.*, 2013). Tourism is a very important driver in many regions and is responsible for a great increase of pressure in coastal areas. Continued human uses and pressures in coastal zones will have an important impact on the future evolution of the coastal ocean's carbon budget.

Coastal areas intensively and multiply used by humans is an anthrome, defined by artificial constructions linked to human settlements, industry, aquaculture, or infrastructure that transforms coastal habitats (Lazarus, 2017). These include a) coastal defences (breakwaters, groynes, and jetties), b) coastal protection (seawalls, bulkheads, and pilings), c) floating docks, e) artificial islands, f) dumping and mining areas, g) artificial structures for energy (including renewable energies) and h) port development and coastal support. Population growth, industrial and tourist development, pollution, habitat and biodiversity loss, changes in access rights, markets and technology and increasing drivers of global change are threatening the future sustainability of coastal areas. Although many of these changes occur in other ecosystems, they are particularly concentrated on the coast.

People living in the coastal areas and particularly poor coastal communities, have adapted to transformations in coastal ecosystems. But now they face an environment of increased competition from high-density and industrial uses, in which access to the resources they depend on is becoming more and more restricted. Additionally, future sea-level rise is also putting pressure on coastal areas. Coastal management needs to encompass decisions of which uses to regulate, which uses to promote, and which NCP are most important to citizens and businesses (Loomis *et al.*, 2014) to provide for sustainable use of the resources of the coastal areas, by addressing trade-offs between conflicting multiple uses.

There is an urgent need for a holistic coastal zone management approach (integrated, multiple use oriented) to provide mediation through administrative procedures, public hearings and facilitated dialogue, for stakeholders (including coastal communities and local and central governments) to be represented in negotiations. Strengthening the integration of IPLCs and ILK in multiple use planning and management in the coastal areas is essential to long-term sustainability of coastal areas (Lockie *et al.*, 2003).

CHAPTER **2.3**

STATUS AND TRENDS – NATURE'S CONTRIBUTIONS TO PEOPLE (NCP)

EXECUTIVE SUMMARY

1 **Nature underpins quality of life by providing basic life support for humanity (regulating), as well as material goods (material) and spiritual inspiration (non-material) (*well established*) {2.3.1, 2.3.5}.** We classify nature's contributions to people (NCP) in 18 categories: (a) regulating environmental processes that affect filtering pollutants to provide clean air and potable water, sequestering carbon important for climate change, regulating ocean acidification, protecting soil quality, providing pollination and pest control, and reduction of hazards. For example, marine and terrestrial ecosystems are the sole sinks for anthropogenic carbon emissions, with a gross sequestration of 5.6 gigatons of carbon per year (the equivalent of some 60 per cent of global anthropogenic emissions), (b) nature plays a critical role in providing food and feed, energy, water, medicines and genetic resources and a variety of materials fundamental for people's physical well-being and for maintaining culture. For example, the combined market value of livestock and fisheries was nearly $1.3 trillion in 2016; more than 2 billion people rely on wood fuel to meet their primary energy needs; between 25–50% of pharmaceutical products are derived from genetic resources; and some 70 per cent of drugs used for cancer are natural or are synthetic products inspired by nature; (c) non-material contributions, such as inspiration and learning, physical and psychological experiences, and supporting cultural identities (Section 2.3.1). Tourism to protected areas, for example, generates an estimated $600 billion annually. Regulating, material, and non-material contributions of nature are not independent; they are linked through both positive and negative interactions. These contributions occur in the present and will also be important as conditions change into the future. Therefore, nature is essential in (d) maintaining humanity's ability to choose alternatives in the face of an uncertain future.

2 **Creation of knowledge from different sources, whether indigenous and local knowledge (ILK) or from scientific organizations, have made significant contributions to NCP and good quality of life (*well established*) {2.3.1, 2.3.2, 2.3.3, and 2.3.4}.** ILK has enhanced NCP through identification of natural medicinal resources, agriculture, and materials, and by providing a diversity of conceptualizations of nature linked to non-material NCP. ILK has contributed to learning and identity, as well as patterns of ecologically-friendly management systems within biodiversity-rich landscape mosaics that favor diversity of habitats and pollinators, fertile soils, and maintenance of future options. The scientific approaches used to assess and measure NCP have increased understanding of ecosystems, biodiversity, and their contribution to good quality of life. Scientific approaches can be grouped into six major classes, based on the particular features of each NCP: evaluation of (a) biophysical processes; (b) ecological interactions; (c) habitats and land cover types; (d) direct material use of organisms; (e) human experiences and learning; and (f) diversity of life on Earth. Greater integration of multiple knowledge systems shows promise for improving use and scaling of NCP impacts. In this chapter, we performed a systematic review of more than 2000 studies of NCP trends during the past 50 years, considering knowledge from ILK as well as scientific organizations.

3 **Most NCP are co-produced by biophysical processes and ecological interactions with anthropogenic assets such as knowledge, infrastructure, financial capital, technology and the institutions that mediate them. However, some NCP, such as the maintenance of options from the pool of genetic diversity available on earth, are produced with little to no human contribution (*well established*) {2.3.1, 2.3.2}.** For example, marine and freshwater-based food is co-produced by the combination of fish populations, fishing gear, and access to fishing grounds {2.3.3}. Co-production of nature's contributions changes in response to human drivers {2.3.2}. For example, conversion of vegetated land to paved surfaces or bare soil reduces the potential for natural water filtration, while management to improve the functional composition of filtering vegetation or building artificial treatment wetlands increases it. The degree to which anthropogenic assets are used in the co-production of NCP varies among and within NCP and may vary across space and time.

4 There is an important distinction between potential NCP, realized NCP, and output of co-production (*established but incomplete*) {2.3.1, 2.3.2}. Potential NCP is the capacity of ecosystems to provide NCP, while realized NCP is the actual flow of NCP that humanity receives. For example, the extent to which vegetation filters pollution to regulate water quality (a **realized NCP**) depends on pollution type and levels, rates of water flow, and the filtration capacity of nature (**potential NCP**). Water quality (the **output of co-production**) depends on the relative rates of pollution and filtration as well as whether pollution feeds back to degrade vegetation and soil filtration capacity. The installation of a water filtration facility will increase the output of co-production and modify the impact on good quality of life. The distinction between potential and realized NCP highlights the importance of maintaining current biodiversity for future options.

5 Since 1970, trends in agricultural production, fish harvest, bioenergy production and harvest of materials have increased – which are 3 material contributions from nature that result in production of marketed commodities, but 14 of the 18 categories of contributions of nature that were assessed, mostly regulating and non-material contributions, have declined. The regulation of ocean acidification showed no consistent global change (*established but incomplete*) {2.3.5}. For example, materials such as production of industrial timber has increased to 608 million m^3 in 2017 (+48% relative to 1970 levels), while its import value has increased more than sixfold (US $2.6 billion in 1970 to US $16.6 billion in 2017). Similarly, the value of agricultural crop production ($2.6 trillion in 2016) has increased approximately threefold since 1970 and raw timber harvest has increased by 45 per cent, reaching some 4 billion cubic meters in 2017, with the forestry industry providing about 13.2 million jobs. In contrast, emission of air pollutants (e.g., $PM_{2.5}$), has increased in many parts of the globe affecting air quality. Only about a tenth of the global population is estimated to breathe clean air, leading to an estimated 3.3 million premature deaths annually, predominantly in Asia. Indicators of regulating contributions, such as soil organic carbon and pollinator diversity, have declined, indicating that gains in material contributions are often not sustainable. Currently, land degradation has reduced productivity in 23 per cent of the global terrestrial area, and between $235 billion and $577 billion[1] in annual global crop output is at risk as a result of pollinator loss. Moreover, loss of coastal habitats and coral reefs reduces coastal protection, which increases the risk from floods and hurricanes to life and property for the 100 million–300 million people living within coastal 100-year flood zones.

1. Value adjusted to 2015 United States dollars taking into account inflation only.

6 The trend in the output of co-production of many NCP differs from the trend in potential NCP and realized NCP. In general, trends for potential NCP are more negative than those for output. Potential NCP has declined since the 1970s for 14 of the 18 NCP, while others show contrasting trends among proxies of the same NCP (*established but incomplete*) {2.3.1, 2.3.5}. For example, agricultural production (output of co-production) has been increasing worldwide, attributed in part to greater agrochemical consumption, but the capacity of nature to support food production (potential NCP), including pollination, pest control, genetic diversity for crop breeding, and the production of wild food has decreased. Furthermore, all taxa of wild crop relatives have decreased, with an estimated 16–22% of species predicted to go extinct and most species losing over 50% of their range size. Another example, as anthropogenic air or water pollution increases, nature provides more filtration (realized NCP increase), but filtration capacity is limited leading to declines in air and water quality (output of co-production).

7 Declines in potential NCP affect both current and future output of co-production and realized NCP (*established but incomplete*) {2.3.2}. The world has lost approximately 8% of total global soil carbon stocks, reducing productivity in 23% of global terrestrial area. Similarly, lost species affect many NCP; for example, global loss of wild pollinators affects a wide range of plants, including major crops. In addition, around 20% of known medicinal species are currently threatened, affecting the large portion of the global population who rely on natural medicines as well as affecting the potential to identify new medicinal compounds. Some declines in NCP can be recovered with ecosystem restoration while other declines are irreversible.

8 Some increases in material NCP are not sustainable (*well established*) {2.3.5}. Harvests exceeding resource replacement rates reduce stocks essential for future supply in many places of the world. This includes overfishing, land expansion for conventional agricultural production, and overharvesting of natural medicinal plants and wood. In the case of marine fisheries, it is estimated that catch has been reduced by up to 36% of its potential in certain areas due to unsustainable fishing practices. This is a trade-off between present and future availability.

9 There are important interactions among NCP, including trade-offs and synergies (*established but incomplete*) {2.3.5}. For example, clearing of forest for agriculture has increased the provision of food and feed (NCP 12) and other materials important for people (such as natural fibers, and ornamental flowers: NCP 13) but has reduced contributions as diverse as pollination (NCP 2), climate regulation (NCP 4), water quality regulation (NCP 7), opportunities for learning and inspiration (NCP 15), and the maintenance of options for the future (NCP 18). However, very few large-scale systematic studies exist on those relationships. Indeed, the decline in pollinator diversity is challenging the production of more than 75 per cent of global food crop types, including fruits and vegetables and some of the most important cash crops such as coffee, cocoa and almonds, rely on animal pollination {2.3.5.2}. Moreover, nearly 90 per cent of wild flowering plant species depend, at least in part, on the transfer of pollen by animals. These wild plants critically contribute to most NCP. On the other hand, natural or semi-natural habitat restoration (NCP 1) can benefit many NCP simultaneously, such as pollination (NCP 2), regulation of air quality (NCP 3), regulation of climate (NCP 4), regulation of freshwater quality (NCP 7), regulation of soil (NCP 8), natural hazard regulation (NCP 9), pest control (NCP 10), learning (NCP 15), and maintenance of options (NCP 18). Globally, there are important initiatives to reduce negative impacts associated with production of material NCP. Synergies also exist, such as those associated with sustainable agricultural practices (e.g., integrated pest management, conservation agriculture, integrated and multi-purposes agroforestry systems, irrigation management, among others) enhance soil quality, thereby improving productivity and other ecosystem functions and services such as carbon sequestration and water quality regulation – many of these synergistic opportunities, which can enhance regulating, material, and non-material NCP, are being implemented already in 9% of worldwide agricultural land. The improvement of pollinator diversity through sustainable intensification could increase crop yields by a median of 24% {2.3.5.2}.

10 **There are large differences in trends in NCP in different parts of the world (*well established*) {2.3.5}.** NCP trend differently across the globe because of differences in direct drivers (chapter 2.1), specifically deforestation and other land conversion, pollution, harvesting, invasive alien species, and climate change {2.3.5}. Because tropical and subtropical regions are undergoing the most pronounced land conversions, primarily for agriculture, potential NCP has declined most in these regions over the past 50 years. For example, deforestation in the tropics offsets the ability of tropical forests to regulate climate (NCP 4).

11 **For a NCP to positively impact quality of life it must be available, accessible, and valued (*well established*) {2.3.2}.** Accessibility and value depend on individual and cultural preferences, institutions, policies, power relations, location, knowledge, experience, demographic variables, and income. The impact on good quality of life depends on the location of people relative to the co-production of different NCP. Cultures may also view nature as contributing to different categories of NCP. For example, the harvest of animal or plant species may contribute to material standard of living by providing nutritious food or providing raw materials for clothing or shelter, while particular animals and plants play a central role in cultural identity or spiritual practices in certain cultures but not others {2.3.2.4}.

12 **Many NCP that are co-produced in one place impact quality of life in regions far away (*well established*) {2.3.5}.** For some regulating NCP, this is because their impacts are inherently global, such as climate regulation. The maintenance of future options is also a global benefit, such as in the case of drug discovery. For many NCP, however, distant impacts occur because goods are moved across the globe. Flows of resources both direct (e.g., commodities) and indirect (e.g., virtual water) can shift the burden and benefit of NCP co-production to distant communities.

13 **Many of nature's contributions to people are essential for human health (*well established*) and their decline thus threatens a good quality of life (*established but incomplete*) {Section 2.3.4}.** For example, there are at least four means by which NCP impact human health: (a) dietary health-nature provides a broad diversity of nutritious foods, medicines, and clean water, including the fact that 840 million individuals lack access to enough calories, but an even larger number, 2.1 billion, fail to access sufficient food of a quality for good health of which biological diversity is a key component; (b) environmental exposure (e.g., reduce levels of certain air pollutants), which includes the health risk associated with degradation of environmental quality, such as air and water pollution flagged as fifth and ninth in terms of global risk by the Global Burden of Diseases study, respectively; (c) can help to regulate disease and the immune system (i.e., exposure to communicable diseases), for example, reducing ecological complexity and diversity concentrates disease vectors and risk, whereas diversified communities dilute risks; and (d) psychological health through improve mental and physical health through exposure to natural areas, for example, visitation rates to national parks, or urban green spaces all suggest strong happiness or psychological well-being values associated with nature.

14 **Impacts of declining NCP vary among people and geographies. Although important examples exist, a systematic assessment of impacts across social groups is not possible because studies are scarce (*well established*) {2.3.5}.** NCP with variable impact include: (a) coastal protection: the loss of mangroves exposes coastal communities to storm damage more so than people who live inland; (b) food and medicine are more available to people in areas with little direct access, such as urban areas, and to those with market access, such as those with higher income; (c) psychological experiences: urbanization can increase isolation of people from nature by

decreasing direct access and thus decrease the mental health benefits of nature; (d) pollinator loss will likely have a larger impact on human health in areas with micronutrient deficiencies, such as Southeast Asia, where 50% of the production of plant-derived sources of vitamin A requires biotic pollination {2.3.5.2}; (e) despite increasing food production, leading to production levels high enough to satisfy the caloric needs of all people on earth, around 11% of the world population is undernourished and at the same time 39% suffer from obesity; and (f) changes in pollination (NCP 2), pest regulation (NCP 10), and soils (NCP 8) are likely of greater importance for commercial farmers, while regulation of freshwater quality (NCP 7) and regulation of ocean acidification (NCP 5) are likely of greater importance for commercial fishers {2.3.5.3}. In addition, contributions that benefit some people may do so at a cost to others, such as when food production reduces downstream water quality.

15 **Most of nature's contributions to people are not fully replaceable, and some are irreplaceable (*established but incomplete*) {2.3.2}.** Loss of diversity, such as phylogenetic and functional diversity, can permanently reduce future options, such as the domestication of wild species that might be domesticated as new crops and/or-be used for genetic improvements of existing ones {2.3.5}. People have created substitutes for some other contributions of nature, but many of them are imperfect or financially prohibitive {2.3.2.2}. For example, high-quality drinking water can be realized either through ecosystems that filter pollutants or through human-engineered water treatment facilities {2.3.5.3}. Similarly, coastal flooding from storm surges can be reduced either by coastal mangroves or by dikes and sea walls {2.3.5.3}. In both cases, however, built infrastructure can be extremely expensive, incur high future costs and fail to provide synergistic benefits such as nursery habitats for edible-fish or recreational opportunities {2.3.5.2}. Substitutes for natural medicines are often financially prohibitive: an estimated 4 billion people rely primarily on natural medicines for their healthcare, mostly in lower income countries. Accounting for the wide range of benefits provided by many of NCP decreases the extent to which human-made alternatives make good substitutes. For example, hand pollination might partly replace the pollination role of wild animals for some crops, but it cannot replace pollination of wild plants nor the cultural value of pollinator species. More generally, human-made replacements often do not provide the full range of benefits provided by nature {2.3.2.2}.

16 **Studies linking co-production and impact on quality of life are scarce. For some NCP, there is a gap between what is commonly measured for the output of co-production and what is most important for impact on good quality of life. Assessing the impact on good quality of life requires synthesis and integration across all NCP (*well established*) {2.3.3, 2.3.5}.** Environmental sciences to date have focused on people's impacts on nature and ecosystem processes. More data is available to characterize either co-production or good quality of life, but there are few studies on the links between the two. For example, in large regions of the world, conventional agriculture is oriented to crop production that does not contribute directly to food security and nutrition (e.g., oil palm, soybean, maize or sugar cane for biofuels or industrial uses). Furthermore, while current food production largely meets global caloric needs, it fails to provide the dietary diversity, notably in fruits, nuts, and vegetables, required in a low health risk diet. Non-biophysical measures and multiples values held by different users groups need to be considered in assessment of good quality of life. Integrated evaluation of good quality of life will highlight the importance of enhancing multiple NCP in the long-term.

2.3.1 INTRODUCTION

This section reviews evidence about the current status and trends of nature's contribution to people (NCP) and highlights how changes in nature can have a profound impact on people's quality of life. NCP is defined to include both positive and negative contributions to good quality of life for which nature is a vital, but not necessarily the sole, contributing factor.

Nature contributes to good quality of life in many ways, from providing the basic life support system for humanity to providing material goods and spiritual inspiration. This section describes 18 categories of NCP that cover a wide range of direct and indirect contributions to humanity (see **Table 2.3.1**) (Díaz *et al.*, 2018). These contributions include the regulation of environmental conditions such as regulation of climate, air, water, and oceans; the provision of material goods such as energy, food, medicines, and raw materials; and non-material contributions such as opportunities for learning, inspiration, and spiritual, cultural, and recreational experiences that underpin quality of life. Each NCP can contribute to quality of life in multiple ways. For example, the provision of food can contribute both to material standard of living as well as to cultural practices and social relationships. The 18 categories of NCP included here capture widely agreed contributions of nature to quality of life. Though the 18 NCP cover a wide array of values and concepts, they do not include all potential values of nature, such as the value of nature for its own sake.

In focusing on NCP to connect nature and good quality of life, this section distinguishes between several closely related concepts **(Figure 2.3.1)**. There is a critical distinction between "potential NCP" and "realized NCP" (Hein *et al.*, 2016; Jones *et al.*, 2016; Villamagna *et al.*, 2013). Potential NCP is the capacity of an ecosystem to provide NCP. For example, a productive marine ecosystem may support abundant fish populations, which could in turn support a vibrant fishery that provides food for human consumption. But without anthropogenic inputs such as boats and fishing gear, and time and effort invested in harvesting efforts, the NCP related to harvesting fish will not be realized. Similarly, a terrestrial system with rich soil and favourable climate could support a high-yielding agricultural crop production system, but without farm equipment and labour, crops will not be harvested. Realized NCP is the actual flow of NCP that humanity receives. Realized NCP typically depends not only on potential NCP but also on anthropogenic assets

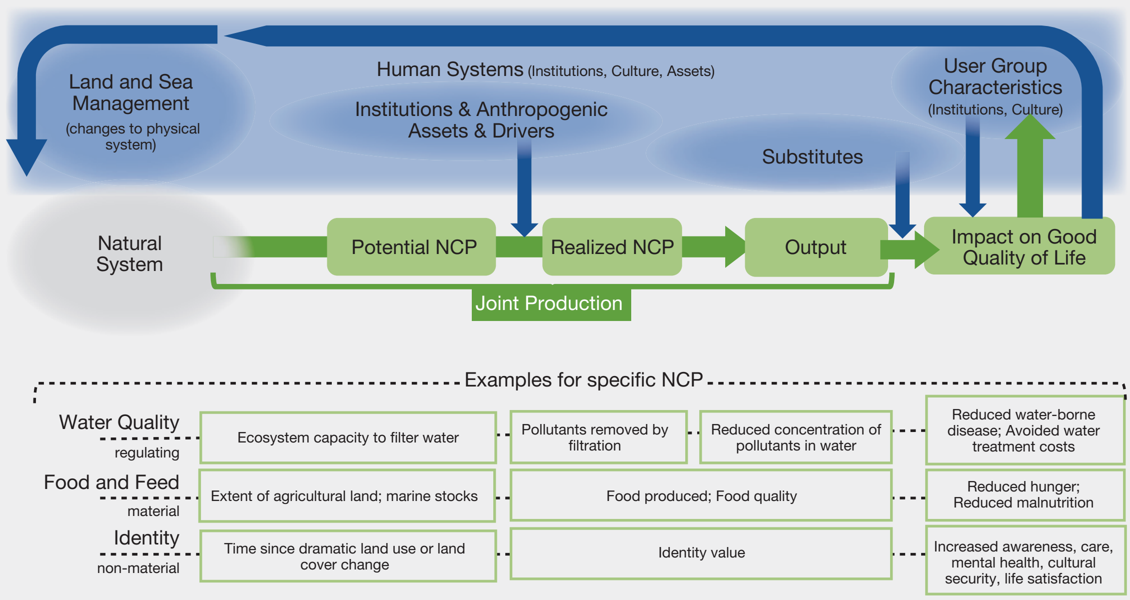

Figure 2 3 1 **Differentiation of Potential NCP, Realized NCP, Output, and Impact on Good Quality of Life.**

The figure illustrates the relationship between potential NCP, realized NCP, output, and impact on good quality of life. Ecosystems, as altered by human management, lead to co-production of potential NCP. The combination of potential NCP along with human inputs leads to realized NCP. For some NCP, there is a difference between realized NCP and output, either because of differences between what the NCP measures and what people care about, or because of substitutes. Outputs as modulated by substitutes, institutions, and culture, impact good quality life. Information about how NCP impact on good quality of life can be used to modify human management and inputs, shown by the arrow from impact on good quality of life to the blue region that represents human systems and back to the green region often via natural systems and joint production.

Table 2 3 1 **List and definition of 18 NCP included in the IPBES conceptual framework, adapted from Díaz *et al.* (2018). See also chapter 1, Figure 1.3.**

	NCP Name	Brief explanation (full definition and evidence provided by NCP in Supplementary Materials - Appendix 2)
1	Habitat creation and maintenance	The formation and continued production, by ecosystems, of ecological conditions necessary or favourable for living beings important to humans
2	Pollination and dispersal of seeds	Facilitation by animals of movement of pollen among flowers, and dispersal of seeds, larvae, or spores of organisms beneficial or harmful to humans
3	Regulation of air quality	Regulation (by impediment or facilitation) by ecosystems of atmospheric gases; filtration, fixation, degradation, or storage of pollutants
4	Regulation of climate	Climate regulation by ecosystems (including regulation of global warming) through effects on emissions of greenhouse gases, biophysical feedbacks, biogenic volatile organic compounds, and aerosols
5	Regulation of ocean acidification	Regulation, by photosynthetic organisms, of atmospheric CO_2 concentrations and so seawater pH
6	Regulation of freshwater quantity, location and timing	Regulation, by ecosystems, of the quantity, location and timing of the flow of surface and groundwater
7	Regulation of freshwater and coastal water quality	Regulation, through filtration of particles, pathogens, excess nutrients, and other chemicals, by ecosystems of water quality
8	Formation, protection and decontamination of soils	Formation and long-term maintenance of soils including sediment retention and erosion prevention, maintenance of soil fertility, and degradation or storage of pollutants
9	Regulation of hazards and extreme events	Amelioration, by ecosystems, of the impacts of hazards; reduction of hazards; change in hazard frequency
10	Regulation of organisms detrimental to humans	Regulation, by ecosystems or organisms, of pests, pathogens, predators, competitors, parasites, and potentially harmful organisms
11	Energy	Production of biomass-based fuels, such as biofuel crops, animal waste, fuelwood, and agricultural residue
12	Food and feed	Production of food from wild, managed, or domesticated organisms on land and in the ocean; production of feed
13	Materials and assistance	Production of materials derived from organisms in cultivated or wild ecosystems and direct use of living organisms for decoration, company, transport, and labour
14	Medicinal, biochemical and genetic resources	Production of materials derived from organisms for medicinal purposes; production of genes and genetic information
15	Learning and inspiration	Opportunities for developing capabilities to prosper through education, knowledge acquisition, and inspiration for art and technological design (e.g., biomimicry)
16	Physical and psychological experiences	Opportunities for physically and psychologically beneficial activities, healing, relaxation, recreation, leisure, and aesthetic enjoyment based on close contact with nature
17	Supporting identities	The basis for religious, spiritual, and social-cohesion experiences; sense of place, purpose, belonging, rootedness or connectedness, associated with different entities of the living world; narratives and myths, rituals and celebrations; satisfaction derived from knowing that a particular landscape, seascape, habitat or species exist
18	Maintenance of options	Capacity of ecosystems, habitats, species or genotypes to keep human options open in order to support a later good quality of life

(e.g., boats and fishing gear, or farm equipment), human labour, and institutions. Institutions can facilitate or prevent access to resources and are often important for determining whether or not potential NCP generates realized NCP. For some regulating services, the degree to which potential NCP generate realized NCP depends on environmental conditions. For example, a forest or grassland may have capacity to filter pollution, but the realized NCP of pollution removal will depend on the amount of pollution coming into contact with the ecosystem. For non-material NCP, an ecosystem may have the potential to support recreation and tourism but if people do not actually go there then it will not yield realized experiences (NCP 16).

For some NCP, there is a further distinction between realized NCP and output, which occurs when what people care about differs from realized NCP. For example, the realized NCP of "regulation of freshwater and coastal water quality" (NCP 7) measures how ecosystems filter nutrients and pollutants from water. Water quality, which is what people care about, depends upon both the input of nutrients and pollutants into the water as well as water filtration provided by ecosystems. If pollution upstream increases, the realized NCP of filtration may increase even though water quality may decline. There may also be a difference between realized NCP and output because of substitutes. For example, food can be produced from natural systems and modified natural systems (e.g., agroecosystems), but food can also be produced in heavily-engineered systems, such as hydroponic production.

The final link moving from left to right in **Figure 2.3.1** is between outputs and impact on good quality of life. Impact on good quality of life depends upon institutions that affect access and use, and upon culture that influences how people perceive, use, and value outputs. Human-made substitutes may influence how the output of NCP impact good quality of life. For example, high quality drinking water can be realized through intact ecosystems that filter nutrients or through human-engineered water treatment facilities. Culture and institutions also mediate the relationship between outputs and impact on good quality of life.

The arrow moving from right to left in **Figure 2.3.1** illustrates how human actions influence potential NCP by altering nature via direct drivers, such as ecosystem management, land-use change, or climate change, the choice of inputs that affects realized NCP, and substitutes for NCP on good quality of life. Information about how human actions influence nature, inputs, or substitutes, and how these in turn impact NCP and impacts good quality of life, can be used to guide human management to ultimately improve quality of life.

To emphasize the intertwined influence of nature and society on the status and trends of NCP, this section uses the term "co-production" to describe how nature and people jointly determine the provision of NCP (Díaz *et al.*, 2015; UN, 2014). For example, a natural medicine requires both that the natural resource is available, and that people have the knowledge to identify and use the healing properties of resources (see NCP 14). The intertwined influence of nature and society is also shown in **Figure 2.3.1**, with nature contributing to potential NCP and human contributions influencing both realized NCP and outputs.

The concept of NCP builds on the concept of ecosystem services (Daily, 1997; Ehrlich & Mooney, 1983; MA, 2005). The IPBES conceptual framework (Díaz *et al.,* 2015) of NCP and its connections to good quality of life shares many similarities with prior ecosystem service frameworks (e.g., Daily *et al.,* 2009; Guerry *et al.,* 2015; Potschin & Haines-Young, 2011), but there are several differences in reasoning and emphasis. In comparison to the discussion of ecosystem services in the Millennium Ecosystem Assessment (MA, 2005), the discussion of NCP emphasizes the central role that culture plays in defining NCP, in different conceptualizations of nature, in human-nature relationships, and in knowledge systems, especially the complementarity between scientific, indigenous, and local knowledge (chapter 1; Díaz *et al.,* 2018). The concept of NCP, as discussed here, also emphasizes the distinction between potential and realized NCP, with realized NCP emphasizing the integration of inputs from humans and nature to co-produce NCP. The discussion of NCP notes that both potential and realized NCP may differ from outcomes. Much of the prior work emphasizes the contributions of nature through ecological functions that supply benefits to people without the emphasis on co-production.

Though many of nature's contributions are positive, there are also negative impacts (similar to ecosystem disservices), such as when elephants trample agricultural crops or mosquitos spread disease (Saunders & Luck, 2016; Shackleton *et al.*, 2016; Vaz *et al.*, 2017). Some ecological interactions simultaneously provide positive and negative contributions. For example, pests feeding on plants are a disservice to food production, but ecological and evolutionary plant responses to these pests are the source of biochemical compounds that have nutritional values, flavour our foods as spices, and are used as medicines.

To support the analyses of these interrelationships, literature evaluating each NCP was evaluated as described in section 2.3.5. The rest of this chapter is divided into five subsections. Subsection 2.3.2 builds on the discussion of **Figure 2.3.1** and provide greater depth on the numerous nature-human interactions on which NCP depends. Section 2.3.3 reviews the concepts and methods for analysing the co-production of NCP. Subsection 2.3.4 reviews concepts and methods for analysing the social, cultural, economic, and political factors that combine with NCP co-production to impact good quality of life. Subsection 2.3.5 is the heart of the chapter and reviews empirical evidence on status and trends of NCP co-production and impact of NCP on good quality of life. Subsection 2.3.6 contains concluding remarks. Detailed assessment of the status and trends for each NCP are included in Supplementary Materials, Appendices 1 and 2.

2.3.2 NATURE AND PEOPLE INTERACT TO CO-PRODUCE NCP AND GOOD QUALITY OF LIFE

Nature and people have always been interconnected in innumerable ways, but awareness of the global implications of such interactions has only become evident in recent decades. Earlier sections of this chapter on Drivers (chapter 2.1) and Nature (chapter 2.2), and chapter 1, illustrate that the actions of people have been affecting nature in numerous and profound ways, from local to global levels. In turn, the literature on ecosystem services and the NCP framework used here focus on the many ways that nature contributes to good quality of life. These efforts to understand the contributions of nature to people fit into a larger context. Literature on social-ecological systems (Berkes *et al.,* 1998; Folke, 2006) and coupled human and natural systems (Liu *et al.,* 2007) have emphasized the co-dependence and co-evolution of people and nature in integrated, complex systems composed of both social (human) and ecological (biophysical) elements. They highlight the feedback between people and nature that shapes both. The importance of these feedbacks has become increasingly apparent as we become aware of the global scale-impact of human activities. Human actions are not only a major driving force of environmental change but the source of change in earth system functioning (Crutzen, 2002), which in turn increasingly affects important aspects of local quality of life (Ellis, 2018; Steffen *et al.,* 2015).

Co-production of food and feed (NCP 12), particularly crop and animal domestication, provides a clear example of the interconnections of nature and people. Domestication is based on an interactive process: wild plants and animals influence human understanding, and people select and domesticate plants and animals (Larson & Fuller, 2014; Olsen & Wendel, 2013). People have selectively bred and dispersed species that have subsequently evolved separately from their wild relatives, allowing agriculture to flourish while fundamentally reshaping human societies and their environment (Stépanoff & Vigne, 2018). The process of co-production uses and creates learning and transmission of knowledge (classifying and naming nature elements, management), experimentation (identifying agronomic or nutritive properties), and decision making (selection of useful traits) (Larson & Fuller, 2014; Stépanoff & Vigne, 2018). Knowledge and practices from Indigenous Peoples and Local Communities (IPLCs) have contributed greatly to domestication and food production; a wide diversity of crop varieties and animal landraces have been developed locally by IPLCs (Altieri *et al.,* 2015). Institutions and governance play a critical role in how crop varieties and knowledge about them are transmitted, and, in turn, these institutions have been shaped by domestication and food production. Institutions and governance range from reciprocity networks based on social exchange and interaction (Coomes *et al.,* 2015; Pautasso *et al.,* 2013) to gene editing technologies so new that regulatory frameworks about ownership have not yet been created (Wolt *et al.,* 2016).

The current state of nature is an important, but not the sole, determinant of quality of life (Guerry *et al.,* 2015; Joly, 2014; Raudsepp-Hearne *et al.,* 2010b). In fact, most contributions from nature to good quality of life derive from interactions between nature and people, including the use of various types of anthropogenic assets, along with the institutions that govern their access, use, and distributive benefits (UN, 2014). Anthropogenic assets include built infrastructure, machinery, and structures, as well as knowledge (including

Table 2 3 2 **Examples of the Functions of Institutions.**

Provide rules regulating property rights for users, management rights, and distributive benefits	Define forms of sanctions and conflict resolution mechanisms
Spread costs	Bring together social, financial, and institutional resources
Achieve economies of scale	Determine needs on a broad scale
Attract expertise	Assess risk
Achieve competence	Apportion and augment NCP
Perform oversight and resource monitoring	Perform quality control
Set prices for non-market goods	Maintain and improve infrastructure
Address non-market social needs	Guiding private enterprise/markets

indigenous and local knowledge systems, technical or scientific knowledge, formal and non-formal education, and experience), technology (both physical objects and procedures), and financial assets. Governance institutions, cultural and spiritual beliefs, and practices can also influence and shape NCP.

Fisheries provide a good example of the complex interactions of nature and people that determine the impact of nature's contribution to good quality of life. The contribution of a fishery to the quality of life of a coastal community depends on interactions between fish abundance, local fishing assets, and the institutions setting rules and norms for access and distribution of fish. Fish abundance itself depends upon the health and productivity of marine and coastal ecosystems and on past fishing activity that impacted marine and coastal habitats and the abundance, diversity, and evolution of fish populations and communities (e.g., Berkes, 2012; Schindler *et al.*, 2010). In addition to fish abundance, the contribution of the fishery to quality of life depends on the effort, knowledge, and experience of the fishers, their fishing equipment (boats, nets), and their economic organization and culture that helps to determine the value and importance of the fish harvest to the community. In addition, institutions and governance that determine access and distribution of benefits play a key role in ensuring long-run sustainability of the fishery and the community (Costello *et al.*, 2008; Gutiérrez *et al.*, 2011; Ostrom, 1990). Some of the important roles that institutions play are listed in **Table 2.3.2**.

2.3.2.1 Co-production of NCP by nature and people

Co-production describes how nature and human management combine to make various NCP available. While acknowledging the critical role of abiotic factors such as topography and climate, the focus here is on the contribution that living nature makes in affecting the availability of NCP.

Human management that affects ecosystems offers a rich set of options for maintaining and improving the co-production of NCP. Such management practices include ecosystem restoration, moderating human actions to be less destructive of ecosystem processes important in the co-production of NCP, and biodiversity-rich agroecosystems that maintain ecological processes. Management actions can also facilitate and enhance co-production of NCP, such as adding filter strips between farms and waterways, designing agricultural systems that maintain crop evolutionary processes and high level of associated biodiversity, replanting grasses to stabilize sand dunes, and xeriscaping. Human management can benefit by borrowing ideas from nature and using them in different applications, such as installing green roofs, use of chemical compounds from nature to produce new medicines, or the invention of new products through biomimicry. However, some human actions, such as emissions of air and water pollutants or conversion of natural habitat for human dominated land uses, negatively impact ecosystem processes and damage or degrade the potential for providing NCP. Such negative impacts may be the unintended consequences of human actions, but often they result from decisions favouring some types of contributions at the expense of others. Specific outcomes or activities are often privileged, and in producing those outcomes others may be negatively affected, often those which are diffuse, less valued culturally or economically, or valued by a less powerful group of users. For instance, a given constituency may live with high levels of pollution or deforestation in exchange for increased revenue from commodity crops or increased industrial employment, even if pollution and deforestation affect large sectors of society and limit future opportunities.

Changes in nature affect the co-production of NCP through a variety of pathways. Conversion of habitat (e.g., deforestation), land-use patterns (e.g., fragmentation resulting in smaller forest patches), and changes in human use (e.g., increase in hunting animals or gathering plants) all affect the co-production of NCP. For example, above-ground carbon sequestration for climate regulation (NCP 4) is primarily a function of vegetation biomass, so changes that affect biomass affect climate regulation (Pregitzer & Euskirchen, 2004). Change in NCP co-production may occur even if human management is low impact; footpaths can be the most active run-off-generating feature of inhabited montane landscapes (Harden, 1992), potentially affecting the regulation of water flow (NCP 6). Some NCP are highly dependent on specific species or communities. Co-production of food (NCP 12), for example, requires specific edible and appealing species (e.g., grapes for wine production) and genetic diversity (e.g., different varieties of grapes) for dietary, cultural, and economic reasons.

There is considerable diversity in how different groups integrate ecosystem processes with human actions to co-produce NCP. Many indigenous and non-indigenous societies, referred to in this report as Indigenous Peoples and Local Communities (IPLCs), consider themselves to be integrated elements of nature and nature as an integrated element of culture (Descola, 2013; Sanga & Ortalli, 2003). Because indigenous territories represents ~38 million km^2, over a quarter of the world's land surface (Garnett *et al.*, 2018),and at least twice the area if local communities are considered (see chapter 1), IPLCs managed landscapes generate many and diverse NCP. Other social groups, such as farmers and herders in both high and low income countries, depend closely on nature but may vary in their interactions with nature in their level of use of anthropogenic assets, particularly technology. At the other end of the spectrum, there are many groups whose livelihoods depend only indirectly, albeit equally fundamentally, on nature and whose local environment is largely transformed by human interventions, such as many urban dwellers, who depend on the continuous, mostly external, flow of water and food.

There is substantial interaction among NCP, as they are often jointly produced. Trade-offs among NCP co-production can occur when exploitation of one NCP changes nature in such a way that other NCP are negatively affected. For example, conversion of forests or grasslands to cultivated cropland increases food production (NCP 12) but can reduce carbon storage (NCP4), change water distribution and quality regulation (NCP 6 & NCP 7), and reduce pollination (NCP 2) and pest control (NCP 10), negatively affecting agriculture itself (Power, 2010). Agricultural intensification may also negatively impact the diversity of resources, which reduce ability to learn from nature (NCP 15) and will tend to reduce options for future use (NCP 18). Synergies also exist, such as co-production by urban parks of storm water control (NCP 6 & NCP 7), reduction of the urban heat island (NCP 4) and improved mental health (NCP 16) (Keeler *et al.,* 2019).

For some NCP, whether an increase in a measure of co-production is good or bad tends to be consistent across user groups. Increased regulation of pests (NCP 10) benefits agriculture and reduces vector-borne disease. For other NCP, whether an increase is desirable or not depends on conditions and on who the beneficiaries are. Natural infrastructure that reduces downstream flooding (NCP 6), for example, might be positive if damage to streamside homes is decreased but negative if floodplain agriculture is starved of sediment and nutrients delivered by flood waters. The effectiveness of NCP co-production should be evaluated in comparison to the co-production of NCP under an

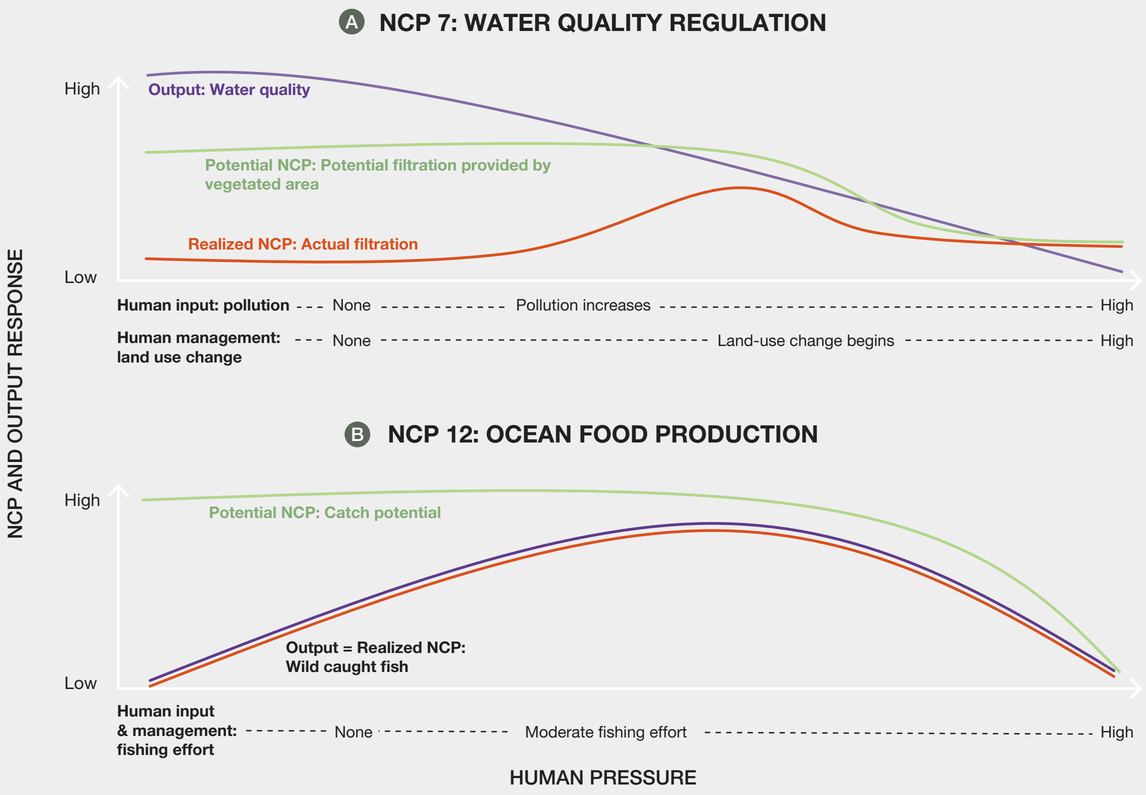

Figure 2 3 2 **Response of Potential NCP, Realized NCP, and NCP Output to External Pressures.**

Examples of changes in local co-production of potential NCP, realized NCP, and the output as human pressure increases. In A, pollutant load increases from left to right, as does land use change. The potential of nature to filter water (green line) decreases as people convert vegetation. Realized water filtration (red line) is low at the left, because there is no pollution to filter. As pollution increases, realized water filtration increases. As land use change decreases potential filtration, realized filtration also decreases. Eventually land use change ceases; water quality continues to decrease as pollution increases because realized filtration has saturated. Extremely high pollution loads could also degrade the potential NCP. In B, fishing effort increases fish catch, which is both the realized NCP and the output. As fish catch increases, catch potential, the potential NCP, decreases, and realized NCP drops as a result.

alternative landscape or management approach (Brauman, 2015). For example, in a vulnerable geography, a large storm will cause a storm surge regardless of the condition of coastal habitat, but differences in the severity and extent of flooding could be attributed to intact mangroves or seagrass beds (NCP 9) as well as to the distribution of human assets (Arkema *et al.,* 2017).

Co-production of both potential and realized NCP change in response to human drivers **(Figure 2.3.2)**. For example, conversion of vegetated land to paved surfaces or bare soil reduces the potential for natural water filtration (NCP 7), and management to improve the functional composition of filtering vegetation or building artificial treatment wetlands increases the potential NCP. Realized NCP changes in response to both potential NCP and human inputs. For example, if there is little pollution in water, vegetation removes very little pollution, and so the realized NCP of actual water filtration is small. As the human input to water pollution increases, so does filtration, but only to a point (Bouwman *et al.,* 2005; Smith *et al.,* 2003; see Appendix 2-NCP7). Changes in the output, water quality, are a function of both changes in land management that change the potential of a landscape to filter water and changes in human inputs of pollution. Even if realized water filtration is large, pollutant loads could still overwhelm filtration capacity, leading to low quality water. Similarly, for provision of food from the ocean (NCP 12), potential catch is a function of ocean productivity, which is related to both the natural system and human management including fishing itself. Realized catch of wild fish changes with both potential catch and the amount of fishing effort. Realized catch increases with fishing effort but decreases as overfishing causes the potential NCP to decline. In this case, output and realized NCP are the same – amount of wild-caught fish (see Appendix 2-NCP 12).

2.3.2.2 Anthropogenic substitutes for NCP

Anthropogenic substitutes for NCP are human-created or human-mediated processes that provide alternative ways to satisfy human needs and desires that partially or completely replace an NCP. For example, water filtration facilities can substitute for water purification provided by ecosystems (NCP 7) in providing clean drinking water (e.g., Ashendorff *et al.,* 1997; National Research Council, 2000). Substitutes could replace the NCP of pollination (NCP 2), such as when hand pollination replaces wild pollinators (Garibaldi *et al.,* 2013). Substitution for pollination could also entail replacing agricultural crops that require animal pollination with crops that do not. A good substitute for an NCP is characterized by its ability to match or exceed the contribution of the NCP, including consideration of changes in access and redistribution of benefits across different user groups, without incurring additional cost. What may be a sufficient substitute for some, for example artificial flavours and fragrances, may result in a significant loss in the contribution to good quality of life for others with different cultural values and preferences.

For some NCP, there may be no good substitutes. 'Critical natural capital' is comprised of components of nature that contribute to good quality of life for which there are no good substitutes so that loss of these components necessarily implies a decline in quality of life (Ekins *et al.*, 2003). For example, the loss of a forest or other natural habitat might cause a loss of identity or sense of place for people for whom the forest had special meaning or significance (Olwig, 2004; Plieninger *et al.*, 2015b). Even when substitutes exist, they may be imperfect or impose significant costs. For example, loss of nutrient filtration capacity of ecosystems may require expensive water filtration facilities downstream to provide clean drinking water (Chichilnisky & Heal, 1998; National Research Council, 2000). In the design of new drugs, use of natural compounds known to be active in traditional medicine can be a more efficient starting place than invented de novo compounds (Newman & Cragg, 2012).

Imperfect substitution may arise because components of nature jointly contribute to multiple NCP. Human-engineered substitutes can often be designed replace a narrowly defined function of nature, but these may fail to replace all natural functions that contribute to a range of NCP. For example, declines in wild pollinators have impacts on plants well beyond crops and may cause declines in plant species that depend on pollination as well as other species that depend on those plants (Brodie *et al.*, 2014; Potts *et al.*, 2016).

Recognizing that the future may be different from today in surprising ways argues for preserving options for the future (NCP 18). A precautionary approach to ecosystem manipulation is often the best way to maintain a full array of potential and realized NCP. The future co-production of NCP may depend on the maintenance of current genetic and evolutionary diversity within and among species.

2.3.2.3 Impact of NCP on good quality of life

The impact of NCP on good quality of life depends both on co-production, which determines the availability of NCP (reviewed above), and on numerous cultural, social, economic, political, and institutional factors that determine how NCP are accessed and utilized and their importance and value to people. Even with the same access to NCP, the impact on good quality of life may be quite different for different groups of people. Groups with different culture, history, experience, education, income, or other factors may use and value NCP quite differently (e.g., Díaz *et al.,* 2018; Pascual *et al.,* 2017). Different cultures may also view nature as contributing to different categories of NCP. For example, the harvest of animal or plant species may contribute to material standard of living by providing nutritious food or providing raw materials for clothing or shelter, while particular animals and plants play a central role in cultural identity or spiritual practices in certain cultures but not others.

Distribution among groups in society

An important question in discussing the impact of NCP on good quality of life is impact on whom. Though overall trends in NCP, and the aggregate value of NCP, are important for policymaking, understanding the distribution of impacts of NCP on the quality of life for different social groups is critical to address social justice concerns (Adekola *et al.,* 2015; McAfee, 2012; McDermott *et al.,* 2013). Nature's contributions affect major social groups in different ways, with some specific contributions being much more important for some groups than others. For example, changes in pollination (NCP 2), pest regulation (NCP 10), and soils (NCP 8) are of greater importance for commercial farmers, while regulation of freshwater quality (NCP 7) and regulation of ocean acidification (NCP 5) are of greater importance for commercial fishers. For many combinations of NCP and major social group there is considerable heterogeneity of impacts by region, and even for different groups even within the same region (e.g., different income classes or ethnic groups).

Impact on good quality of life may occur far from where an NCP is co-produced, and preferences and governance in distant societies may affect co-production. Globalization and trade moves goods that are co-product in one region to consumers around the globe. People living in urban areas rely on food, materials, and medicinal products (botanical medicines) that are produced or grow naturally thousands of miles away. Global nature tourism influences the management of some nature conservation areas. Demand from far away can increase pressure on ecosystems and have detrimental impacts on the local environment and on co-production of NCP (Chi *et al.,* 2017; Wolff *et al.,* 2017). A number of recent analyses study the environmental impacts of trade by tracking the carbon embedded in traded goods (e.g., Davis & Caldeira, 2010; Peters *et al.,* 2012, 2011; Sato, 2014) or the amount of water embedded in traded goods (e.g., Allan, 2003; Dalin *et al.,* 2012; Hanasaki *et al.,* 2010). Flows of resources both direct (e.g., commodities) and indirect (e.g., virtual water) can shift the burden and benefit of NCP co-production to distinct communities (MacDonald *et al.,* 2015). Other linkages between co-production in one region and impact on quality of life occur because of environmental interconnections. For some regulating NCP, impacts are global, such as climate regulation (NCP 4). For other NCP there are important impacts downwind (air quality regulation, NCP 3) or downstream (water quantity regulation, NCP 6, and water quality regulation, NCP 7).

The way people benefit from nature depends on where and how they live and how institutions support or inhibit access to NCP. Though overall trends in NCP, and the aggregate value of NCP, are important for policymaking, understanding the distribution of impacts of NCP on the quality of life for different social groups is critical to address social justice concerns (Adekola *et al.,* 2015; McAfee, 2012; McDermott *et al.,* 2013). Knowing how changes in NCP differentially impact disadvantaged social groups, such as subsistence harvesters in tropical forest regions or low income peri-urban residents, can help devise more effective strategies for poverty alleviation. Disadvantaged groups in regard to NCP refer to those groups who have less access to nature and to different types of anthropogenic assets (i.e., forms of capital: natural, human, manufactured, social, financial capital) that allow them to benefit from nature. The distribution of NCP strongly affects the quality of life of disadvantaged social groups in societies with strong power asymmetries. For this reason, a greater disaggregation of social groups to better understand the distribution of NCP is needed, particularly where levels of inequality are high (Daw *et al.,* 2011).

Factors leading to unequal distribution of NCP include geographic location, nearness of nature, social status hierarchies and power relations, property and access regimes, and availability of anthropogenic assets needed to co-produce NCP. Property and access regimes are types of institutions with strong influence on NCP distribution. Recent research has emphasized the multiple mechanisms by which social groups gain access to nature and benefit from NCP, beyond formal institutions, notably property rights (Cole & Ostrom, 2010). Whether land is either or a combination of private, public or common property, rights interact with the biophysical context to shape basic access to nature and NCP. Furthermore, social groups may gain complementary access through their differential ability to access anthropogenic assets such as knowledge and technology, and different groups have varying power to impose their choices, such as the ability of influential groups to modify institutions (Ribot & Peluso, 2003). This in part explains why formal and informal institutions ("rules-in-use") often work against disadvantaged groups and limit how much these groups can benefit from nature (Seghezzo *et al.,* 2011).

A spatially explicit analysis of NCP along with access rules and infrastructure can help to identify which groups will likely benefit the most from co-production of NCP. Some analyses have linked provision of NCP to beneficiary groups (e.g., Bagstad *et al.*, 2014). It is important to note that human use of ecosystems creates feedbacks that modify landscapes and affect the availability and accessibility of NCP beyond immediate users and for the future. Knowing who wins and who loses due to changes in the co-production of and access to NCP, and the mediating role of institutions and governance regimes, is a highly policy relevant area of research that requires strong interdisciplinary science.

Characteristics of user groups mediate the impact of NCP on good quality of life

A fully developed analysis of the impact of NCP on good quality of life would report on the consequences for specific user groups. User groups could be based both on livelihoods (subsistence gatherers, subsistence and commercial farmers, subsistence and commercial fishers, pastoralists, commercial ranchers, commercial foresters, mining, energy production, commercial and manufacturing), as well as residence location (rural, semi-urban, urban, coastal, inland, forest, grassland, desert, etc.), or other forms of social categorization. Studying the impacts of NCP on quality of life, as well as doing so by major user group, is still a relatively new area of research. There are many gaps in our knowledge base and information to report on trends by user group is quite limited for many NCP. Though this was the initial goal of this assessment, there was insufficient evidence reported in the literature at present to support a comprehensive and systematic reporting of the impacts of NCP on good quality of life by different user groups.

Issues in aggregating data and information on NCP across and within groups

A global level assessment requires aggregate information. For NCP, 'aggregation' refers to assessing the benefits of NCP to a large group without explicit recognition of distributional patterns of benefits within the group. Reporting the aggregate monetary value of NCP at a national or global level contains useful summary information and can be helpful for seeing broad scale trends. However, reporting aggregate value also hides information about distribution of NCP impacts among groups and be poor indicators of the contribution to poverty alleviation (TEEB, 2010). Similarly, national aggregate indices of income (such as gross domestic product, GDP), do not address inequality variations in income and do not give proper attention to the condition of the poorest members of society (Piketty, 2014; Ravallion, 2001). Likewise, value reporting tends to overlook non-material NCP that are difficult to express in monetary terms.

One potential approach to taking account of distributional concerns but retaining the benefits of aggregation is to use equity weights that assign different values to different groups based on their relative wealth. Equity weights place a higher value on benefits to disadvantaged groups. Use of equity weights in climate change give greater importance to climate impacts in low income countries (e.g., Anthoff *et al.,* 2009; Azar & Sterner, 1996). To date, the literature on NPC has not used equity weights to analyse distributional consequences of changes in NCP. In general, there is a great need for analysis of NCP to take greater account of the distribution of impacts.

Distribution over time and discounting

Many changes to ecosystems have long lasting effects that can affect the flow of NCP for both current and future generations. Consideration of NCP values that occur in the future raises the issue of how to compare present versus future values. A standard approach in economics to questions of aggregating values over time is to use discounting but discounting for long-run environmental issues that affect quality of life for future generations also raises a host of ethical issues (Portney & Weyant, 1999; TEEB, 2010). The simplest and most common form of discounting is to use a constant exponential discount rate. However, many critics of discounting think that it puts too little weight on future values, especially those that occur in the distant future. A second issue with discounting is the lack of clarity on what discount rate should be used, as even slight differences in discount rates matter hugely. For example, the value of $1 million 100 years in the future is worth $6.7 thousand at a 5% discount rate but only $0.045 thousand at a 10% rate. Suggestions for discount rates range from greater than 10% for risky business investments to less than 1% for long-term investments in public goods that affect everyone. Several prominent economists have recommend using very low discount rates for projects with long lasting environmental impacts (e.g., Stern & Taylor, 2007; Weitzman, 1998) but other prominent economists have argued for use of much higher rates that are closer to market interest rates (e.g., Nordhaus, 2007a, 2007b). Most value estimates reported in section 2.3.5 are for the current value of NCP so discounting is not an issue. However, the issue is very important for management and policy decisions that affect the long run, such as with climate change or habitat protection policies.

Another issue is that the future NCP are not likely to be simple extrapolations of present NCP. For instance, elements of biodiversity might not provide an NCP in the present but may provide important contributions to good quality of life in the future. Such notions are at the heart of option value (NCP 18). Changing values, knowledge, and conditions, mean that NCP provided by the preservation of current biodiversity may only become apparent in the future.

2.3.3 METHODS FOR MEASURING CO-PRODUCTION OF NCP

Measurement of the co-production of NCP varies across studies and among NCP, as NCP are often evaluated in ways most relevant to their local context (Díaz *et al.*, 2018). For many NCP, studies of related biophysical or social phenomena exist but must be re-interpreted to evaluate their implications to NCP co-production. For example, the field of landscape hydrology is well developed but has generally focused on run-off prediction under various weather regimes, not specifically on the role of vegetation in regulating water flow (Brauman *et al.*, 2007). Similarly, much existing work in agronomy measures phenomena such as pollinator diversity or density without measuring the contribution of pollination to people, such as its impact on yield or nutritional value (Potts *et al.*, 2016). Even fewer studies consider interactions between multiple NCP (TEEB, 2015).

The impact of most NCP can be measured by ILK-based methods in addition to scientific approaches. Biocultural indicators simultaneously measure nature as well as practices associated with nature (e.g., species used for medicine, crops and their dietary roles, a forest and its role in protecting water sources). These indicators reflect how people benefit from nature for their well-being but also how humans contribute to ecosystem health or well-being (Sterling *et al.*, 2017b). These indicators also reflect how IPLCs engage in learning processes that contribute to co-production of NCP through knowledge generation (e.g., about the behavior of animals with importance as food, or changes in crop phenology that indicate climatic changes, or the development of crop varieties or landraces). These methods apply across all NCP and are addressed below in stand-alone section 2.3.3.2 to highlight the potential use of ILK to measure NCP.

Chapter authors systematically evaluated how co-production of NCP is measured following guidelines for systematic review (Collaboration for Environmental Evidence, 2013). Authors summarized theory of NCP co-production for each NCP in Section 2.3.3.1 (below) and in Appendix 2. Below, we group our findings about the approaches used to assess and measure NCP co-production in the literature into six major classes of scientific research and six approaches based on ILK.

2.3.3.1 Scientific approaches to measuring NCP co-production

Based on review of the literature on NCP and the biophysical and social processes that go into their co-production, we summarize six general approaches to measuring co-production of NCP.

i. *Biophysical processes*: Regulating NCP describe the influence of ecosystems and their biological constituents on biophysical processes that influence good quality of life. Direct measures of regulating NCP are usually difficult, as abiotic factors interact in the co-production of many regulating NCP. It is, however, often possible to measure specific biophysical processes important for NCP supply. These include measurement of air pollutants deposited on plant surfaces (NCP 3); carbon sequestered in growing forests (NCP 4) and algae (NCP 5); water transferred to the atmosphere or to aquifers by plants (NCP 6); changes in water quality attributable to filtering by riparian forests (NCP 7); the rate of soil erosion with and without vegetation (NCP 8); and root density that may stabilize rocks and soil on steep slopes (NCP 9). Models are frequently used to scale up local studies of biophysical processes and to integrate biophysical processes with other factors important for generating NCP.

ii. *Ecological interactions*: Some NCP are the outcome of ecological interactions, such as fruit and seed setting (NCP 2) and disease prevalence and crop damage (NCP 10); their production can be assessed based on the abundance and diversity of organisms involved in co-production, e.g., pollinators and seed dispersers (NCP 2); or pests, pathogens, predators, and competitors (NCP 10). These NCP can also be measured by the outcome of the ecological interaction. For example, the amount and quality of pollen deposited on the stigma (NCP 2) could be measured, as could impacts of pests in the presences of natural enemies (NCP 10). Outputs of co-production may also be evaluated, such as enhanced crop production (NCP 2) or reduced food waste (NCP 10).

iii. *Habitats and land cover types*: For many NCP, the presence of a specific habitat or land use type is interpreted to mean that an NCP is being co-produced. For example, hedgerows and forest fragments alongside farms are assumed to provide pollination (NCP 2) and riparian buffers to provide water filtration (NCP 7). Assumptions about land cover functionality are generally extrapolated from local studies that measure a biological process or identify particular organisms or the outputs of ecological interactions.

iv. *Direct material use of organisms*: Material NCP are based on the direct use of organisms to provide for material human needs. Material NCP include bioenergy (NCP 11); food (NCP 12); materials (NCP 13); and medicine (NCP 14). Realized material NCP can be directly measured through the amount and quality produced or consumed; potential NCP can be measured as the extent and suitability of land, freshwater, or marine areas for production, as well by the diversity of organisms with potential use for material human needs.

v. *Human experience and learning*: Non-material NCP stem from the interactions of people with material and non-material elements of nature. Measures of the interactions between people and nature, such as proximity of people and nature in everyday life (NCP 15), tourism and recreation in outdoor areas (NCP 16), or customary or ritual use of sacred sites (NCP 17), are one way of quantifying them. Proxies may also be used, such as the economic value of patents resulting from bio-based innovations (NCP 14), the use of bio-inspired materials (NCP 15), co-existence of cultural (linguistic) and biological diversity (NCP 15), investments in equipment for outdoor activities (NCP 16), and time since major land use change (NCP 17). These proxies are not thought to be representative but represent early attempts to quantify non-material NCP.

vi. *Diversity of life on earth*: A diversity of organisms and ecosystems are required to co-produce NCP. Diversity can be assessed using metrics such as phylogenetic diversity and intra-specific diversity to quantify biological variation that underpins the provision of options for the future (NCP 18).

NCP measures are relatively consistent in some cases (e.g., NCP 4 carbon sequestration), but for many NCP there are no globally consistent data on which to base estimates of status and trends (Crossman *et al.,* 2013). Specific methods for assessing NCP are still evolving, tend to be locally relevant, and as a result are often difficult to compare globally (Díaz *et al.,* 2018). Measurements of regulating NCP are inconsistent among studies and thus difficult to compare (Ricketts *et al.,* 2016). For material NCP, measures of realized co-production are more robust, largely because many associated NCP have sales and trade data, though these may not reflect NCP co-production important to IPLCs and other marginalized or less visible communities. Moreover, these data do not provide information about potential NCP because they fail to reflect unsustainable resource harvest or NCP quality (Hein *et al.,* 2016). For non-material NCP, qualitative approaches assessing human experiences and learning from nature are deeply informative and are generally locally specific and highly contextual, again making comparison among studies difficult (Daniel *et al.,* 2012; Milcu *et al.,* 2013; Pascual *et al.,* 2017; Satz *et al.,* 2013). At the global level, non-material NCP are often measured by proxies representing the state of nature that contributes to experience and learning, such as extent of high biodiversity landscapes or existence of sacred sites (Berkes, 2012; Garnett *et al.,* 2018; Verschuuren *et al.,* 2010).

2.3.3.2 Indigenous and Local Knowledge approaches to measuring NCP co-production

Indigenous Peoples and Local Communities have long histories of observation, experimentation, prediction, testing, investigating causality, and interpretation and explanation (Cajete, 2000). In comparing indigenous science with western academic science, the Worldwide Indigenous Science Network remarkss "'Indigenous scientists are an integral part of the research process and there is a defined process for ensuring this integrity" (Worldwide Indigenous Science Network, 2018). In general, indigenous practice emphasizes relational accountability to other people and to living and non-living things; making connections and understanding systems as a whole, including spiritual components, rather than through deconstruction into constituent parts; and seeking balance with the natural world rather than controlling it (Tengö *et al.*, 2017; Toledo, 2001). Relationality is the idea that relationships form reality, and relational accountability can be put into practice through choice of research topic, methods of data collection, the form of analysis, and the presentation of information (Wilson, 2008). In contrast to dominant science practices in which researchers stand outside the system as impartial observers, indigenous and other science perspectives acknowledge that there is an inextricable relationship between knowledge and the people and processes that produce it. This means that IPLC have unique insight into NCP, not only because they may have knowledge of NCP that differs from scientific approaches but also because they understand the co-production and impact of NCP differently. This has led to many studies showing that it is important to protect indigenous and local knowledge of NCP, the people themselves, and their ways of life if NCP are to be maintained (Friedberg, 2014; McGregor, 2004).

To measure NCP from an IPLC perspective, data about ILK of NCP co-production must must also be co-produced. This is done in a variety of ways, including participatory approaches, ethnographic research, participatory mapping, experimental economics, and social surveys (Alcorn, 1996; Ding *et al.,* 2016). Different types of dialogue workshops for the Americas, Asia-Pacific, Europe and Central Asia, and Africa dialogues, organized around IPBES assessments, have contributed to bring some of this knowledge to the assessment process through inviting a large set of representatives of IPLCs and researchers working jointly with the latter, and through facilitating a process of integrating their views and processes. Other sources of ILK measures of NCP has been conveyed in the scientific literature, scholarly and popular texts, and in reports by NGOs by and working with IPLCs. Broader recognition of the importance of ILK in environmental management, although greatly improved since the onset of the Convention on Biological Diversity in 1992 (article 8j), is still emerging. Global level syntheses of ILK contributions to co-production of NCP are scant because ILK is place-based and embedded in local cultural perspectives, so scaling up is challenging. However, integrating ILK with scientific approaches has allowed some important aspects of ILK to be upscaled. For example, although traditional agroforestry systems are locally based, global data mapping agroforestry systems across the planet (Zomer *et al.,* 2009) makes it possible to quantify the extent and impact of such practices at the global level. IUCN, through a process of dialogue and also systematic mapping, has produced global maps showing the diversity of sacred sites (Verschuuren *et al.,* 2010). Other examples include the management of regionally-relevant watersheds (Critchley *et al.,* 1994; Tsatsaros *et al.,* 2018; Wilson *et al.,* 2018) and the maintenance of agrobiodiversity of regionally and globally important crops and animals (Howard, 2010; Veteto & Skarbø, 2009).

ILPCs communicate their understanding of NCP co-production in a variety of ways, including:

i. *Nomenclature:* Names used in ILK designate species and intraspecific species diversity. Names communicate information about material NCP, their diversity and distribution across landscapes (e.g., crop diversity), and about non-material NCP, such as learning (e.g., phenology of each crop and its capacity to face water scarce situations, the names of specific pollinators and the species they prefer (Simenel, 2017), and predators of specific fruit trees). Compiling nomenclature can generate understanding of habitat intactness, distribution of a resource across a landscape, capacity of the latter to face risks and hazards, and drivers of change. Local lexicon may differentiate types and categories, for instance of food, medicines, and materials, and may also provide cues identifying species that are genetically distinct (learning NCP 15), have distinctive nutritional or medicinal qualities, or prefer a given environment. Work with local specialists, such as traditional healers, can provide precise information on threats to useful medicinal species (e.g., Ghimire *et al.,* 2008) and the drivers of change, specific areas that are more vulnerable, and species that are more vulnerable in relation to specific harvesting practices (Ghimire *et al.,* 2008). Linguistic analysis can indicate changes in biodiversity, including long-term changes. For example, reference to specific species in narratives and oral traditions in places where those species no longer exist indicate extinctions, and in some places this ILK indication of extinction has been associated with physical evidence of the loss of megafauna. Such evidence cross-checked with archeozoological archives and thorough linguistic analysis show that data from local narratives indeed correspond to periods of loss of megafauna as well as changes in human practices (Wehi *et al.,* 2018).

   ILK nomenclature also provides information about exchanges between proximate and distant social groups. For example, the pre-Columbian transfer of sweet potato varieties to the Pacific Islands by Amerindians from South America, was first established by linguists using IPLC terminologies who identified Quechua names used by Pacific peoples, a first finding that eventually led to scientific hypotheses tested genetically (Roullier *et al.,* 2013).

ii. *Narratives:* Narratives that relate the status of connections between plants, animals, fungi or soil microorganisms in ILK are a measure of biotic interactions which are often critical to the co-production of NCP. The narratives relate how connections are effectively favoured or used to identify functional roles of species directly or indirectly useful to people. These narratives generally link to co-production systems such as trees with symbiotic endomycorrhizae or ectomycorrhizae with fertilization roles on soils or that increase availability of carbon and water for the trees, and wild pollinators recognized for their specific roles (Couly, 2009; IPBES, 2016). Similarly, in the Mediterranean, biotic interactions between trees and ectomycorrhizae are understood through observation of the "brulé", a barren area located at the base of trees that host truffles, illustrate learning from nature (NCP 15) (Aumeeruddy-Thomas *et al.,* 2017). Narratives of infrequent events also provide a measure of hazards and the contribution of nature to mitigating hazard impact. These narratives collect observations of nature and NCP and transmit this information intergenerationally, a process that contributes to learning as well as mitigating hazards. For example, IPLCs in the Indian Ocean region drew from traditional myths and oral history about past tsunamis to identify ways in which nature helped mitigate tsunami impact and thus survive a recent disaster (Adger *et al.,* 2005; Arunotai, 2017; McAdoo *et al.,* 2006). IPLCs' narratives about ways nature can be managed to reduce the impact of past shocks include not only tsunamis (Becker *et al.,* 2008; Lauer, 2012; McAdoo *et al.,* 2009; Walshe & Nunn, 2012); but also fire (Bradstock *et al.,* 2012); extreme weather (Janif *et al.,* 2016); cyclones (Paul & Routray, 2013; Veland *et al.,* 2010; Yates & Anderson-Berry, 2004); floods (Mavhura *et al.,* 2013); heavy rain (Chang'a *et al.,* 2010; Roncoli *et al.,* 2002); and ENSO-induced frost (Waddell, 1975). Drawing on this place-based knowledge, 'hazardscapes' have been developed where the frequency, impact, and warning signs of hazards as well as the ways that nature mitigates hazard impact are documented through participatory techniques (Cronin *et al.,* 2004) and hazard mapping (Cadag & Gaillard, 2012; Tran *et al.,* 2009). In another example, comparative geological and linguistic analysis of Australian Aboriginal stories and narratives have showed that they include accurate information about sea-level rising floods occurring over 7,000 years ago (Nunn & Reid, 2016). As in science, understanding past events is important to predicting the future and to adaptation. More details about the relationship between ILK and hazard mitigation are provided in Supplementary Materials, Appendix 1.

iii. *Taboos and sacredness*: The presence of taboos or of sacred sites such as groves, landscapes, mountains, or objects indicate NCP ranging from direct material use to identity (Dudley *et al.,* 2010; Samakov & Berkes, 2017; Thorley & Gunn, 2008). For example, in Oceania, material and non-material contributions of marine resources are indicated by reef and lagoon tenure, which is used to manage access in defined territorial waters and serves to protect marine resources (Johannes, 1978). Similarly, concepts of taboo or (sacred) prohibition indicate human use of nature and are themselves manifestations of non-material benefits of nature (Bambridge, 2016a, 2016b; Conte, 2016; Dixon, 2016; Ottino-Garanger *et al.,* 2016; Torrente, 2016; Veitayaki, 2000). Recording taboos and sacredness in relation to nature elements is a measure of a given society's identity through intricate linkages to nature.

iv. *Practices of nature management.* IPLC practices, including changes in society and development of rules to address over-harvesting (Wehi *et al.,* 2018), also measure NCP co-production. For example, ILK practices to enhance pollination, ranging from fire management to strategic placement of crops, indicate the importance and extent of pollination (IPBES, 2016).

v. *Land use and land cover:* The existence of high biodiversity landscapes and sacred sites nurtured by ILK indicates the co-production of a wide range of NCP. These landscapes can be measured as land managed by IPLCs (Garnett *et al.,* 2018) as well as by detecting land use patterns such as large-scale agroforestry (Brondízio, 2008) or shifting cultivation systems (Heinimann *et al.,* 2017). The present-day composition of many ecosystems and culturally and economically important landscapes may also be a measure of ancient management by IPLCs; for example, anthropogenic soils (terra preta) formed by ancient Amerindians settlements suggests their knowledge of benefits provided by improving soil fertility (NCP 8) and also affects present-day Amazonian biodiversity (McMichael *et al.,* 2014). Measuring the geographic extent of practices and landscapes that ensue from past and present ILK activities is a key way to measure NCP. Contemporary soil management systems by IPLCs such as terraced cultivation landscapes in Asia, in high mountain areas, and in the Mediterranean region are areas where communities can explain how such practices contribute to soil improvements through decrease of erosion.

vi. *Direct elicitation*: IPLCs have spoken directly about their knowledge of NCP, especially during Dialogue workshops that were published regarding the 4 regional assessments. One such example is the role of Ficus species in agricultural areas in Madagascar; planting Ficus in fields increases agricultural productivity and overall biodiversity (Rafidison *et al.*, 2017). While describing such practices, traditional communities refer simultaneously to the ecological role of these trees, which attract many birds and lemurs, and also the connection to ancestors who planted them, and the power that they possess that can influence people's lives. Further, their leaves are often medicinal and their latex useful for hunting. 'ILK thus involves a holistic approach that does not separate the economic and tangible from the intangible and the overall ecological value. Because ILK tends to be holistic and consider social and ecological systems as interdependent, elicitation of values of nature are often linked to human-well-being. ILK, through elicitation of IPLCs often articulate and measure threats to NCP and their own well-being in an intertwined way because ILK understands interconnections between ILPC and nature and the impacts of nature on their lives in a holistic way that does not dissect one element and its specific use. ILK may thus measure changes in NCP by identifying processes that affect biodiversity and their lives concomitantly, including industrial development, forced displacement and migration, and climate change.

While scientific and ILK measures may seem distant depending on the type of question or goal, there are potential synergies between science and various types of indigenous and local knowledge systems. For example, agroforestry practices developed by and valued according to local ILPC measures also have high production outputs and may include carbon sequestration potential, both of which can be qualified and quantified in different but complementary ways (Altieri & Nicholls, 2012). Co-produced systems like agroforestry that provide critical NCP requires information about practices, such as soil management techniques, and how and where they are deployed, based on measures coming both from scientific research and ILK (Altieri *et al.,* 2015).

2.3.4 METHODS FOR MEASURING IMPACT OF NCP ON GOOD QUALITY OF LIFE

This section evaluates how different material and non-material relationships between people and nature influence the perception, importance, and value of NCP across social groups. Different societies and cultures, and different individuals within them, may consider their relationship to nature and the importance of various NCP in quite different ways. This leads to multiple dimensions of value, which are discussed in depth in chapter 1. We take a broad view of how value should be discussed and quantified. This requires mobilizing multiple methods to describe, characterize, and measure the value of nature's contributions to good quality of life. Value concepts can be expressed in terms of environmental (biophysical), economic, or social criteria, or in terms of specific outcomes such as health, income, or livelihoods. This section describes several approaches to measuring the value or importance of NCP, including methods that focus on biophysical measures with a clear link to quality of life, methods from the health sciences, methods from economics to quantify the market and non-market value NCP, and social, cultural, and holistic approaches to describing the impact of NCP on good quality of life.

2.3.4.1 Biophysical measures of NCP

Biophysical measures are often used to assess the co-production of NCP. Biophysical measures also can be useful for measuring impact on good quality of life as long they are clearly linked to measures of human well-being. For example, measures of the amount of natural habitat in agriculture are useful for predicting pollinator abundance, which can be linked to food production and improved nutrition. But for NCP with a complicated relationship between biophysical quantities and good quality of life, or that are valued quite differentially by different groups, biophysical indicators only provide a partial measure of the impact on good quality of life. For example, increases in water flow may be good or bad depending upon whether there is currently water shortage (drought) or excess water (flood) affecting different groups of people. Another challenge is that biophysical measures may have course spatial resolution that does not include indicators grounded in indigenous and local knowledge better able to capture local needs (Sterling *et al.*, 2017a). For example, a measure of water quality cannot capture Maori values such as the role of particular water bodies in creation stories, maintaining local species habitats, used in access routes, or potential use by future generations (Harmsworth *et al.*, 2016).

Even when a biophysical measure is clearly tied to an impact on quality of life, the biophysical measure alone rarely is sufficient for describing the value of the NCP (Martín-López *et al.,* 2014). For example, knowing how intact ecosystems can reduce flooding potential downstream is an important component of the value of flood reduction. But without knowing the number of people exposed or impacted downstream the biophysical measure of the value of flood reduction is incomplete (Watson *et al.,* 2019). Also, biophysical measures should account for changes in the relative scarcity of nature. NCP that become scarcer over time relative to human-made substitutes will become more valuable (Drupp *et al.,* 2018; Krutilla, 1967).

Careful thought is required to translate biophysical measures into measures of impact on people and their quality of life (Keeler *et al.,* 2012; Polasky & Segerson, 2009). Olander *et al.* (2018) describe the development of benefit relevant indicators (BRIs), which are well-defined measures of outcomes valued by people because they have a direct impact on well-being. Some biophysical measures, such as those relevant to human health, make good benefit relevant indicators because they have clear value to people and may also encapsulate several aspects of quality of life at once. Epidemiological models can be used to translate environmental exposures to pollutants into health risks. Such methods have been applied to assess the health benefits of reduction in exposure to air pollution (e.g., Arden Pope & Dockery, 1999). For many biophysical measures, however, there are several intermediate steps needed to translate the biophysical measure into a measure of impact on human quality of life. For example, the contribution of an ecosystem to nutrient filtration can be measured in biophysical terms by the reduction in nutrient loadings to water bodies. But information about nitrate loading alone is insufficient for understanding impacts on human health. Translating nutrient loadings to impacts on quality of life also requires knowledge of how changes in nutrient loadings affect water quality (levels of nutrient concentrations), how people use water downstream (drinking water, irrigation, recreation, etc.), and how nutrient concentrations affect these uses (e.g., whether for drinking water there is a water treatment plant that removes excess nutrients prior to drinking so that extra nutrients increase cost, or are there health effects from drinking lower quality water). In addition, current biophysical outputs do not necessarily represent future biophysical outputs. For example, climate change may cause changes in precipitation patterns and run-off leading to different nutrient loadings with consequent impacts on various downstream uses (Runting *et al.,* 2017).

Another disadvantage of using biophysical measures is that it can be hard to compare impacts involving multiple NCP.

Assessing and comparing the impact on good quality of life of different outcomes of co-production typically requires either measuring outcomes in the same unit or knowing people's preferences for alternative outcomes (Mastrangelo & Laterra, 2015). For example, clearing land to plant crops will increase food production but often results in lower water quality and reductions in carbon storage. Whether this increases or decreases overall value depends on the relative value of food versus water quality and carbon storage. Biophysical measures are essential to support evidence-based decision-making but are not able to fully capture diverse value systems.

In sum, biophysical measures are essential for defining potential NCP, realized NCP, and output, but need to be clearly linked to human well-being in order measure to impact on good quality of life. But biophysical measures alone are rarely sufficient for evaluating impact on good quality of life. In section 2.3.5, we combine biophysical measures with measures of human use to define impact on good quality of life.

2.3.4.2 Contributions of NCP to Health

NCP impact health through: (1) dietary health, (2) environmental exposure, (3) exposure to communicable diseases, (4) hazard risk reduction including exposure to extreme weather, drought or fire, (5) psychological health, and (6) use of natural compounds in medicinal products and biochemical compounds. For the first four risk factors, disability-adjusted life years (DALY) are frequently used to assess overall disease burden. DALY's are expressed as the number of years lost due to ill-health, disability or early death. The measure is becoming increasingly common in health impact assessments (Murray, 1994). Because risk originates from multiple interacting factors, including human drivers of environmental degradation, disaggregating the contribution of nature to reducing health risks remains highly complicated.

Diet: Diet related disease is the leading cause of premature mortality, both in terms of non-communicable diseases such as diabetes and cardiovascular illness, but also including hunger and starvation (Forouzanfar *et al.,* 2015; Wang *et al.,* 2016). Food production (NCP 12) and multiple supporting NCP are central to providing sufficient, healthy, delicious, and culturally relevant foods. While global food systems are able to produce sufficient calories for today's population (increase in NCP 12 production), many people do not consume a healthy diet. Lack of income leading to under-consumption continues to be a problem in many poorer areas while over-consumption leading to obesity is an increasing problem in many middle and upper income countries. Diet composition is also important. Increased consumption of fruits and vegetables is associated with reductions in various diseases such as cardiovascular disease (Ness & Powles, 1997). The diversity of global food supply is falling (decrease in the number of species supporting NCP 12; Khoury *et al.,* 2014; Lachat *et al.,* 2017)

Environmental Exposure: Environmental exposure includes the health risk associated with degradation of environmental quality. Notable health risks include air pollution (Cohen *et al.,* 2017) and water pollution, flagged as fifth and ninth in terms of global risk by the Global Burden of Disease respectively (GBD 2017 Risk Factor Collaborators, 2018). NCP do not account for totality of risk from poor air and water quality because much pollution originates from anthropogenic sources. Nature can filter out pollutants to some extent, though some recent studies show that nature can also concentrate and trap pollutants, which may occur with trees in urban settings (Keeler *et al.,* 2019). An increasingly small proportion of the global population depends directly on clean water provided by nature, and a decreasing number of freshwater bodies have water quality of sufficiently high standard for human consumption without treatment. Most air pollution comes from vehicle emissions, power generation; other industrial sources, agricultural emissions; residential heating and cooking; re-emission from terrestrial and aquatic surfaces; chemical processing; and natural processes (IARC, 2016). Emissions from agriculture, biomass burning, and natural processes are often exacerbated by loss of nature, suggesting an avoided cost of maintaining nature intact. Health impacts of exposure can be quantified by assessing population exposure to poor water or air quality metrics. Measures can include exposure risk levels or can be extrapolated to economic measures of avoided treatment cost or avoided mortality and morbidity (Viscusi & Aldy, 2003).

Exposure to communicable diseases and increased risk of contagion: Nature's contribution to exposures to communicable disease and reductions in exposure is mixed. Habitats and alteration of habitat affects the population of vectors of disease. Risk is highest when human populations are proximate to vectors or when they create environments that are conducive to vectors (e.g., creation of stagnant pools of water and increased risk of malarial infection). Disease risk increases when the vector and human habitat overlap such as is the case with human encroachment on forest systems for Ebola or the proximity of irrigated agricultural systems as with malaria. Risk maps can be developed which highlight localities where exposure risk is high (e.g., Anyamba *et al.,* 2009).

Hazard risk reduction: Environmental change, including climate change, is increasing human risk exposure to natural hazards (e.g., floods, fires), exposure to extreme weather events, and heat stress for outdoor workers (Guha-Sapir *et al.,* 2016; McMichael *et al.,* 2006). Intact nature can reduce risks by intercepting or buffering the impact of extreme events or by providing shelter or relief, described in NCP 9 (e.g., reduced wave or storm surge impact, reduced urban heat island effect that reduces heat exposure for urban residents). At times, however, change in nature in response to environmental change can increase risk (e.g., climate change driven fires increase exposure to poor air quality, loss of life to fire, and delayed risk of mass erosion driven by loss of soil retention). Specific measures include the direct loss of life due to a hazard in question. Contributions can be assessed by evaluating nature's contributions to reducing loss of life or to the value of property damage (Barthel & Neumayer, 2012).

Psychological well-being: Interaction with nature are hypothesized to improve mental health (Frumkin *et al.,* 2017), though reviews of scientific findings have been inconclusive about the extent of this effect and the elements of nature which might provide it (Gascon *et al.,* 2015; Haluza *et al.,* 2014; Lee & Maheswaran, 2011). Exposure to the outdoors does likely improve learning and well-being for children (Gill, 2014; McCormick, 2017; Tillmann *et al.,*

Box 2 3 2 **Human health and microbiota.**

Microbial organisms living in and on the human body (in the gut, oral and nasal cavities, and reproductive and respiratory tract), collectively known as microbiota, carry out a range of vital functions and are a key determinant of health (Belkaid & Hand, 2014; Rodrigues Hoffmann *et al.,* 2016; Thomas *et al.,* 2017; Turnbaugh *et al.,* 2007; Wang *et al.,* 2017; West *et al.,* 2015). These organisms (bacteria, viruses, fungi and other organisms) have co-evolved with humans over thousands of years and are important to human survival as they have been found to support several vital functions (Cash *et al.,* 2006; Logan *et al.,* 2016; Nagpal *et al.,* 2014; O'Hara & Shanahan, 2006; Rook *et al.,* 2014; Wang *et al.,* 2017). These microorganisms vastly outnumber our human cells by at least an order of magnitude, with most of them residing in our gastrointestinal tract (Gill *et al.,* 2006; Turnbaugh *et al.,* 2007; Zhu *et al.,* 2010).

It is now well established that the microbiota plays an important role in regulating our immune system (Hooper *et al.,* 2012; Rook, 2013; Rook & Knight, 2015; Round & Mazmanian, 2009). It has also been found to contribute to digestion, nutrition (Adams & Gutiérrez, 2018; Bäckhed *et al.,* 2005; Claesson *et al.,* 2012; Filippo *et al.,* 2010; Kau *et al.,* 2011) and defense against pathogenic organisms and to influence a number of metabolic, physiological, immunological processes (Belkaid & Hand, 2014; Candela *et al.,* 2008; Fukuda *et al.,* 2011; Hooper *et al.,* 2003; Lee & Mazmanian, 2010; Macpherson & Harris, 2004; Sommer & Bäckhed, 2013).

Declines in the abundance and diversity of human microbiota often associated with modern lifestyles have given rise to dysbiosis and associated dysbiosis-related diseases (such as inflammatory bowel disease) (Ehlers & Kaufmann, 2010; Ipci *et al.,* 2017; Mosca *et al.,* 2016; Sommer *et al.,* 2017), thereby contributing to the rising global burden of noncommunicable diseases (Liang *et al.,* 2018; Logan *et al.,* 2016). Factors contributing to these altered patterns of the gut microbial ecosystem include industrialization, urbanization, overuse of antibiotics (Bello *et al.,* 2018; Cox & Blaser, 2015; Khanna & Pardi, 2016; Lange *et al.,* 2016; Sekirov *et al.,* 2010; Tanaka *et al.,* 2009; Verhulst *et al.,* 2008) and chemicals (Claus *et al.,* 2016; Velmurugan *et al.,* 2017), dietary changes (Filippo *et al.,* 2010), childbirth and neonatal practices (Bäckhed *et al.,* 2015; Lynch & Pedersen, 2016), and reduced/limited early-life exposure to microbial diversity in the wider environment (Fallani *et al.,* 2010; Huttenhower *et al.,* 2012; MacGillivray & Kollmann, 2014; Mosca *et al.,* 2016; Prescott, 2013). In particular, these changes in microbial exposures are linked with a rise in inflammatory disorders such as asthma (Ver Heul *et al.,* 2019), allergic (Haahtela *et al.,* 2013; Hanski *et al.,* 2012; Rook *et al.,* 2013; von Hertzen *et al.,* 2011), and other autoimmune diseases (such as multiple sclerosis) (Chen *et al.,* 2016); inflammatory bowel diseases (McIlroy *et al.,* 2018; Sartor, 2008), diabetes (Boerner & Sarvetnick, 2011), cardiovascular diseases and obesity (Boulangé *et al.,* 2016; Tang *et al.,* 2017; Turnbaugh *et al.,* 2006), some cancers (Scanlan *et al.,* 2008; Vétizou *et al.,* 2015) and neurological disorders (Parashar & Udayabanu, 2017; Szablewski, 2018), autism (Bjorklund *et al.,* 2016; Finegold *et al.,* 2002; Li & Zhou, 2016) and psychiatric conditions such as depression (Aerts *et al.,* 2018; Evrensel & Ceylan, 2015; Rook *et al.,* 2014; Thomas *et al.,* 2017).

Proximity to natural and farm environments (in particular those in which traditional farming methods are used sustaining rich microbe environments) reduces the incidence of some inflammatory diseases such as asthma (Mosca *et al.,* 2016; Schaub & Vercelli, 2015; Stein *et al.,* 2016). As a result, higher rates of inflammatory disorders found in some modern cities may be associated with reduced microbial exposure (both in the environment and from contact with animals) (Schaub & Vercelli, 2015; Tun *et al.,* 2017).

These and other findings have implications for the development of targeted interventions such as the restoration of microbial diversity, for example, through dietary changes (Adams & Gutiérrez, 2018; Filippo *et al.,* 2010; Riccio & Rossano, 2018; White *et al.,* 2018), sound antibiotic stewardship (Khanna & Pardi, 2016; Tanaka *et al.,* 2009), traditional medicines (Thakur *et al.,* 2014), and restoration of microbial biodiversity in the environment, including soil and urban environments, to improve, physical and mental health (Aerts *et al.,* 2018; Cryan & Dinan, 2012; Liang *et al.,* 2018; Marchesi *et al.,* 2016; Mills *et al.,* 2017; Rieder *et al.,* 2017; Rook *et al.,* 2013; Rook & Knight, 2015).

2018). Visitation to national parks and urban green spaces are indicators of values associated with nature. Countries that normally top most global happiness surveys are associated with very strong conservation ethics. Happiness and psychological well-being are multidimensional however; security, employment, family, friendship are all important.

Medicinal Products: Many antibiotics, cancer fighting drugs, and painkillers such as aspirin are originally derived from nature (e.g., Salicylic acid is found in willows; the genus *Salix*). IPLCs frequently have specific knowledge and use of natural products, which can serve as their primary source of medicine. The perpetual evolutionary battle between predator and prey, parasite and host, including of microscopic biodiversity (bacteria, fungi), is a dynamic source of novel medicines including new antibiotics to battle antimicrobial resistance. While modern medicines are largely synthesized rather than cultivated, the majority of new medicines continue to be sourced from nature (Newman & Cragg, 2012; Schippmann *et al.*, 2006). Metrics for nature's contribution are in the proportion of novel drugs sourced from biodiversity, the economic value of novel drugs, and/or increased DALY's.

2.3.4.3 Economic valuation of NCP

Economists have developed a variety of market and non-market valuation methods applicable to measuring the value of many NCP (Champ *et al.*, 2003; Freeman III *et al.*, 2014; TEEB, 2010; US EPA, 2009), and there are large databases of estimates of value along with relevant references (Carson, 2011; Van der Ploeg & de Groot, 2010). Applications of economic valuation methods generate estimates of value measured in monetary terms. The three main advantages of applying economic valuation methods to measure the impacts on human well-being are that: 1) impacts on well-being are reported in a common (monetary) metric that allows for comparison across different NCP, 2) measures are readily understood by many decision makers in governments and the private sector, and 3) measures are based on a set of well established methods grounded in economic theory. There are also some significant disadvantages, discussed below.

Economic valuation methods can be readily applied to many material NCP that are embodied in goods bought and sold in markets for which prices exist (e.g., agricultural crops, energy, materials). Even some non-material NCP can be evaluated using evidence from market transactions, such as values associated with recreation and tourism for which the expenses related to travel can be used to estimate the benefits (Freeman III *et al.*, 2014). However, many NCP are not traded in markets, particularly regulatory and non-material NCP, and therefore lack a market price that could be used as a signal of value. In some cases where NCP lack market prices, non-market valuation methods can be applied. These methods can be classified into three broad types: a) revealed preference methods, b) stated preference methods, and c) cost-based methods. Revealed preference methods generate estimates of value based on observed behavior on choices people make. For example, showing that houses located near parks or natural areas have higher property values than similar houses not located near parks or natural areas provides evidence on the value that people place on proximity to parks or natural areas (e.g., Mahan *et al.*, 2000; Sander & Polasky, 2009). Stated preference methods generate estimates of value from responses to survey questions. For example, contingent valuation can be used to ask whether respondents are willing to pay for a certain level of provision of an NCP. Cost-based methods use estimates of the costs of replacing an NCP with a human-engineered substitute. For example, clean drinking water can be supplied by ecosystem processes that filter nutrients and pollutants or by a water filtration facility.

Some NCP, especially non-material NCP such as those linked to spiritual and religious life or supporting identities (NCP 17), generate benefits that are difficult, and perhaps inappropriate, to measure in monetary terms using economic methods (Chan *et al.,* 2012; Daniel *et al.,* 2012; de Groot, 2006; de Groot *et al.,* 2002; MA, 2005; Milcu *et al.,* 2013). Few prior studies evaluate the capacity of nature to provide learning and inspiration (NCP 15), psychological experience (NCP 16), and identity (NCP 17) in monetary terms (Cooper *et al.,* 2016; Daniel *et al.,* 2012). The lack of inclusion of measures of the values of the non-material benefits is an important gap in economic measures of the value of NCP. Various authors approach evaluation of the impact of non-material NCP using other value notions, such as relational (Chan *et al.,* 2016), constitutive (James, 2015), sociocultural (Martín-López *et al.,* 2014), or transcendental values (Kenter *et al.,* 2015; Raymond & Kenter, 2016).

For many NCP in many locations, there are no existing studies that estimate the value of the NCP. Although the use of high-quality primary research is preferred, the realities of limited data and limited resources often dictate that benefit transfer is the only feasible option to estimate values. Benefit transfer is based on the use of valuation studies conducted at particular sites or in specific policy contexts to predict values at other unstudied sites or policy contexts (Johnston *et al.*, 2015). Using benefit transfer enables approximations of economic value to be provided when time, funding, or other constraints prevent the use of primary research to generate estimates of value. When considering the use of primary valuation research versus benefit transfer, the central trade-off is between the resources and time required for the analysis and the level of accuracy in estimated values. Benefit transfers can generally be conducted more easily than primary valuation but can involve significant errors when not done carefully.

Some prior estimates of ecosystem service valuation use a particularly simple form of benefit transfer based on applying a value estimate per unit area of habitat type (e.g., Costanza *et al.,* 1997; Troy & Wilson, 2006). This approach assumes that every hectare of a particular habitat type is of equal value to every other hectare of that habitat type and ignores both ecological and social-economic heterogeneity that is often crucial in determining the value of ecosystem services (Plummer, 2009; Polasky & Segerson, 2009). Other critiques point out that it is invalid to simply scale estimates derived at a small spatial by the amount of total area (Bockstael *et al.,* 2000). Because of substantive issues raised in the literature about benefit transfer based on applying a value estimate per unit area of habitat type, we do not use this approach nor report on estimates of the value of ecosystem services that rely on this approach. This rules out many of the most widely cited monetary estimates of ecosystem services.

Critics of applying economic valuation to NCP raise several issues. First, economic valuation methods may unfairly privilege the wealthy over the poor. Economic valuation depends on willingness-to-pay, and willingness-to-pay depends on the distribution of wealth and income. The poor will not be willing-to-pay as much as the rich even for important NCP simply because they lack the ability to pay. Second, there is evidence that framing issues in terms of markets and money can alter how people value nature (Falk & Szech, 2013; Sandel, 2012). Finally, some critics think it is impossible to capture spiritual and religious values using economic valuation, as such values are fundamentally different from economic values (Cooper *et al.,* 2016; Satterfield *et al.,* 2013; Stephenson, 2008).

In Section 2.3.5, we include economic measures of the value of various NCP, particularly for material NCP, but for other NCP as well where available. Though it is important to include other measures of value of NCP in addition to economic measures, economic measures can be influential with government agencies (e.g., ministries of finance) as well as with the private sector.

2.3.4.4 Social, cultural, and holistic measurements of NCP

Identifying social, cultural, or holistic values (including sociocultural, political, historical, patrimonial, and others) of nature by social-cultural groups across the planet requires understanding the diverse ways in which individuals and groups interact with nature and their differing concepts of quality of life. Local understanding and practices about these relationships influence and are influenced by local modes of conceptualizing nature and related practices and knowledge, which may or may not correspond to a discreet measurable entity (Descola, 2013; Ellen & Fukui, 1996). Nature-culture relationships respond to and affect social norms, values and beliefs, social interactions (languages about nature, classifications, symbols and signs), ways of defining law and justice (including rights of access to resources, tenure, heritage and matrimonial systems), and processes that link the material to the non-material, the tangible to the intangible, and myths and taboos (Descola, 2013; Foucault, 1966; Levi-Strauss, 1966). All these interconnected dimensions may be shared within societies and may be transmitted across generations through social learning, but they may also be contested, disrespected, or actively replaced in the face of new pressures and/or culture change. Notions of a good quality of life are linked to values that are generally local, but also, and increasingly due to media and global trade, include values and expectations from the larger society or even completely different regions (Sterling *et al.,* 2017a). For example, the value of local food systems and their diversity as elements representing the identity of a given society is changing very quickly as trade exchanges at the global level increases the global homogeneity of food diversity used and therefore choices made locally (Khoury *et al.,* 2014).

When there are conflicts about an element of nature, approaches and methods to understand values need to consider their distinct social-cultural contexts. For example, extracting and trading wild medicinal plants to urban consumers may conflict with social-cultural, economic, and health values of people living in source areas who may have an emotional and cultural relationship to place and resources as well as those who depend economically or medicinally on these resources (Cunningham, 1993; Enioutina *et al.,* 2017; Hamilton & Aumeeruddy-Thomas, 2013; Richerzhagen, 2010). Non-material benefits cover a wide spectrum and may be intellectual, spiritual, emblematic, or symbolic (see also relational values; Chan *et al.,* 2016). To understand these values, it is important to work in local contexts because cultural, ecological, economic, and social values are intertwined, and priorities may vary greatly in different geographical regions. This puts emphasis on cultural significance rather than cultural values and emphasizes how people establish significant meaning around components of nature.

One of the key indicators for IPLCs refers to 'connection to land' and 'connection to sea' (Cuerrier *et al.,* 2015; see also CBD), which is a holistic indicator that relates to memory of place and its biodiversity, its role for economic needs, and also to adapting to changing environments such as climate change (McMillen *et al.,* 2014). This indicator can be interpreted as whether community members have the possibility and the right to engage with the land and sea directly by cultivating their ancestral land and hunting or harvesting or fishing in these territories and includes their capacity to adapt and transform to face environmental change (Marshall *et al.,* 2012). Additionally, personal and community connections to land (and sea) facilitate co-production of other NCP such as learning from nature through direct learning or transgenerational transmissions, especially important for children (NCP 15) (Dounias & Aumeeruddy-Thomas, 2017; Gallois & Reyes-García, 2018; Simenel, 2017) and inspiration for instance regarding artistic expression or recreational uses (NCP 15, 16) (Balmford *et al.,* 2015; Wolff *et al.,* 2017).

Integrated approaches to understanding significant cultural meaning related to nature using the idea of connectedness and locally-based approaches consider the following: (1) cultural uniqueness, (2) community reliance on nature that links to livelihoods, incomes, and level of importance for well-being; (3) cultural traditions (connectedness to place, rituals, width of interest across the community); (4) dramatic cultural change (the role of the element of nature considered in periods of dramatic change to address identity, or other sources of meaning). In addition, some integrated approaches consider the resilience of the social-ecological system and their ability to recover, adapt, and transform in the face of environmental change (Folke, 2006).

Due to this complexity and depending on the objectives for evaluating sociocultural and holistic values, a diversity of methods is used, with a major common denominator being linking values to places and developing scoring approaches at the local level. Some of the diversity of methods used are shown below although this is not an exhaustive list. Combinations of several methods are often used:

- Qualitative in-depth and open interviews followed by encoding of discourses for analysing preferences
- Developing narratives in general to understand emotions, sense of place, cultural memory, and situated knowledge (Nazarea, 2016)
- Using maps coupled to field related anthropological and sociological approaches, including understanding social behavior and networks related to a specific type of resource and its geography (Reckinger & Régnier, 2017)
- Analyzing social exchange networks in relation to a specific resource such as seed exchange networks (Salpeteur *et al.*, 2017)
- Analyzing world views and conceptualizations of nature and how this links to specific practices, and evaluating nature classifications through anthropological approaches (Sanga & Ortalli, 2003)
- Free listing and ranking approaches (Martin, 1995)

2.3.5 STATUS AND TRENDS OF NCP CO-PRODUCTION AND IMPACT ON GOOD QUALITY OF LIFE

This section presents information on the status and trends of co-production of NCP and on the impact of NCP on good quality of life. The co-production of NCP is an important determinant of the impact of NCP on quality of life, but impact also depends on anthropogenic assets, institutions, governance, culture, and other social, economic, and political factors. Our analyses attempt to disentangle the effects of changes in nature from changes in human factors on the co-production of NCP, and on impacts on good quality of life, by presenting trends in potential NCP, output, and impact of NCP on good quality of life side by side **(Figure 2.3.3)**. Though the results presented in **Figure 2.3.3** are not causal, showing potential NCP, output, and impact helps to illuminate the main factors related to changes in NCP. Changes in potential NCP arise primarily from changes in nature. In contrast, changes in impact on good quality of life can arise from changes in nature, such as a decline in habitat leading to a reduction in the co-production of an NCP, or from changes in anthropogenic factors affecting the way people use and value an NCP. For example, even with no change in co-production, changes in access rules, human-made substitutes, or cultural norms that change how people interact with nature may cause shifts in how an NCP contributes to good quality of life. **Figure 2.3.3** also helps to illuminate differences between NCP and outcomes that people care about, such as the filtration of air and water pollutants (NCP 4 and 7) versus outcomes of primary interest to people (air and water quality). **Figure 2.3.3** does not include realized NCP. Realized NCP is the same as output for material and non-material NCP. For regulating NCP, realized NCP and output generally are different, with output measures more closely aligned to impacts on good quality of life. For example, when air or water emissions increase, ecosystems may filter more pollution (realized NCP increases), but air or water quality may decline (output decreases). We also show the global distribution of selected indicators relevant to NCP **(Figure 2.3.4)**, and the relative status of NCP across terrestrial biomes **(Figure 2.3.5)**.

Methods & indicators

Chapter authors systematically evaluated literature on co-production of NCP, impacts on good quality of life, and the status and trends for each of the 18 NCP presented in **Table 2.3.1**. To accomplish this, chapter authors developed a standardized template and undertook an expert evaluation following guidelines for systematic review (Collaboration for Environmental Evidence, 2013). In the templates, authors summarized the theory of NCP co-production and impact, and also summarized evidence about the status and trends in NCP. From these templates, authors then summarized evidence supporting global trends in co-production of potential NCP, output, and impact, which are presented in **Figure 2.3.3** with explanation in **Table 2.3.4**. The longer templates and supporting data are contained in Supplementary Materials, Appendix 2. Authors also identified and explained global, distributed data proxies to quantify NCP used to assess status and trends in each IPBES unit of analysis. These units of analysis encompass 11 terrestrial and 6 aquatic biomes and anthropogenic systems ranging from tropical forests to aquaculture areas to urban areas. Specific literature review was conducted for IPLCs and ILK for all NCP, and more extensive evaluations of ILK of climate regulation (NCP 4), soil development (NCP 8), and hazard regulation (NCP 9) are incorporated in the chapter and provided in Supplementary Materials, Appendix 1.

To visualize and quantify NCP status and trends, indicators (Niemeijer & de Groot, 2008) for potential NCP, output, and impact on good quality of life were selected for each NCP. Separate indicators for potential NCP, output, and impact on good quality of life were chosen, as trends in each may differ (Hattam *et al.,* 2015). Candidate indicators were identified through review of the literature on each NCP (see Appendix 2). One to two indicators for each NCP were selected by consensus through dialog among chapter authors. Selection criteria prioritized scientific soundness and IPBES policy relevance (de Groot *et al.,* 2010; Heink *et al.,* 2016; Maes *et al.,* 2018). NCP indicators presented in **Figure 2.3.3** align with indicators in prior assessments for NCP that align with categories of ecosystem services used in prior assessments (Hattam *et al.,* 2015; Shepherd *et al.,* 2016; UNEP-WCMC, 2011). **Figure 2.3.4** includes data only for natural terrestrial biomes; NCP from oceans, freshwater, cultivated areas, and urban areas are not included in this figure. However, such areas, along with natural terrestrial biomes, are addressed in the text below.

Global, distributed data to represent potential NCP, outcome, and impact on good quality of life, relies heavily on biophysical data at present. Some global economic values, particularly for material NCP, are available. However, many indicators of NCP are not readily available globally. More data are available at regional and local levels, including qualitative measures that incorporates observations, tallies, perceptions, desires, visions, and experiences of local

Table 2 3 3 **Global Data Proxies Representing Select NCP presented in Figure 2.3.5.**

NCP	Data Proxies	Citation
NCP 3: Air quality regulation	Leaf Area Index	(Zhu *et al.,* 2013)
NCP 4: Climate regulation	Terrestrial Net Primary Productivity	(Zhao *et al.,* 2005)
NCP 6: Water quantity regulation	Evapotranspiration	(Mu *et al.,* 2013)
NCP 7: Water quality regulation	Bare Area	(Klein Goldewijk *et al.,* 2017)
NCP 8: Soil regulation	Soil Organic Carbon	(IPBES, 2018a; Stoorvogel *et al.,* 2017; Van der Esch *et al.,* 2017)
NCP 9: Hazard regulation	Area of Floodplain Wetlands	(Reis *et al.,* 2017)
NCP 11: Energy	Net Primary Productivity in Forests and on Cultivated Land	(ESA, 2017; Zhao *et al.,* 2005)
NCP 12: Food	Cultivated Area	(ESA, 2017)
NCP 13: Materials	Above Ground Biomass in Forests	(ESA, 2017; Liu *et al.,* 2015)
NCP 14: Medicine	Medicinal Species as a Fraction of Total Vascular Plant Species	(Kreft & Jetz, 2007; data S. Pironon and I. Ondo, see RGB Kew, 2016)
NCP 15: Learning	Geographical Overlay of Linguistic Diversity and Biodiversity	(Hammarström *et al.,* 2018; Purvis *et al.,* 2018; Stepp *et al.,* 2004)
NCP 17: Identity	Rate of Land-Use Change	(Klein Goldewijk *et al.,* 2017)

communities (Sterling *et al.,* 2017a). Few of the indicators proposed in previous research directly refer to existing datasets that are both global and spatially explicitly (de Groot *et al.,* 2010; Feld *et al.,* 2009; Hattam *et al.,* 2015; Heink *et al.,* 2016; Maes *et al.,* 2018; Pongratz *et al.,* 2018), but we aligned with these suggested indicators when possible. Average values were calculated for each data proxy over each biome. The indicators used to create **Figure 2.3.5** are summarized in **Table 2.3.3**.

ILK provides a wide range of indicators of nature (see chapter 2.2) and NCP. The ILK indicators most often used for NCP relate directly to co-production, i.e., interactions between people and nature that determine NCP provision. These indicators include population size, spatial distribution, animal behavior, and phenology of economically and/or culturally important wild plant and animal species, such as hunted animals, medicinal herbs, fodder species, and sacred species (Berkes, 2012; Ghimire *et al.,* 2004; Verschuuren *et al.,* 2010). Quantitative measures of plant and animal species are most often abundance values (e.g., number or density of individuals in a certain area; Ticktin *et al.,* 2018). In some cases, especially for economically important NCP, data may exist on harvest or catch per unit effort, or distance travelled to reach a resource (e.g., distance to firewood or water source). Another important group of NCP indicators from ILK describes the quality of an ecosystem that provides essential resources. For example, ILK may describe the quality of rangelands based on the health of the soil or the density of preferred and palatable species (Yacoub, 2018).

IPLCs often use holistic and fuzzy indicators that are not readily quantifiable (Berkes & Berkes, 2009), making them difficult to summarize and include in a global assessment. ILPC perception and categorization of NCP are often considerably different from the 18 NCP categories shown in **Figure 2.3.3** and **Figure 2.3.5**. Some ILPC indicators are similar to NCP categories used in this assessment. For example, the health of the forest (Caillon *et al.,* 2017) is similar to NCP 1 (maintenance of habitat). However, the IPLC indicator of the health of the forest is broader and more inclusive than maintenance of habitat. Biocultural approaches capture both the ecological underpinnings of a cultural system and the cultural perspectives of an ecological state and thus highlight interactions and feedbacks between humans and their environment (Sterling *et al.,* 2017a). Some IPLC indicators of nature monitor supernatural beings like the presence or encounter rates with supernatural forest dwelling entities (Lyver *et al.,* 2018).

2.3.5.1 Global Status and Trends across NCP

Figure 2.3.3 summarizes global trends in potential NCP, output, and impact on good quality of life based upon a comprehensive and systematic literature review. **Table 2.3.4** provides background for **Figure 2.3.3**. Section 2.3.5.2 discusses the ways trends in NCP differ by IPBES unit of analysis. Section 2.3.5.3 provides a summary discussion for each NCP. Longer and more detailed discussion for each NCP are given in Supplementary Materials, Appendix 2. Appendix 1 provides an assessment of NCP from an ILK perspective when conducted separately from the long descriptions in Appendix 2. Section 2.3.5.4 addresses knowledge gaps. Two NCP, habitat creation and maintenance (NCP 1), and maintenance of options (NCP 18), do not have meaningful distinctions between potential NCP, output, and impact of NCP on good quality of life. For these two NCP we report only on trends in potential NCP. For all other NCP (NCP 2 – 17), we report on status and trends for potential NCP, output, and impact on good quality of life.

Globally, the majority of NCP have experienced a decline in potential NCP (left panel of **Figure 2.3.3**), output (central panel of **Figure 2.3.3**), and impact on quality of life (right panel of **Figure 2.3.3**). Land-use change, climate change, and other major drivers of ecosystem change (see chapter 2.1) have caused changes in nature (see chapter 2.2) that have caused declines in many NCP both in terms of co-production and impact on quality of life.

Trends in Potential NCP

Globally, potential NCP has declined for 14 of 18 NCP. Potential NCP has declined for habitat (NCP 1), regulatory NCP with the exception of regulation of ocean acidification (NCP 2-4, 6-10), medicinal, biochemical and genetic resources (NCP 14), non-material NCP (NCP 15-17), and maintenance of options (NCP 18). Over the past 50 years, agricultural expansion, and to a lesser extent expansion in other human dominated land uses (mining, energy, urban, and built areas), have led to increases in both potential NCP and output of material production dependent on agricultural and other transformed lands for energy, food, and materials (NCP 11-13). The expansion of human-dominated land uses has caused a reduction in the area of forests, grasslands, and other natural habitats. The reduction in natural habitat has been the largest single factor contributing to the decline of potential NCP over the past 50 years. Potential NCP has also declined for elements of material NCP that depend on forests or marine stocks (NCP 11-13). For regulation of ocean acidification, a decrease in potential of terrestrial ecosystems to absorb CO_2 driven mostly by land-use conversion has been offset by an increase in potential to absorb CO_2 in marine systems caused by warming of the upper ocean driving an increase in net primary productivity.

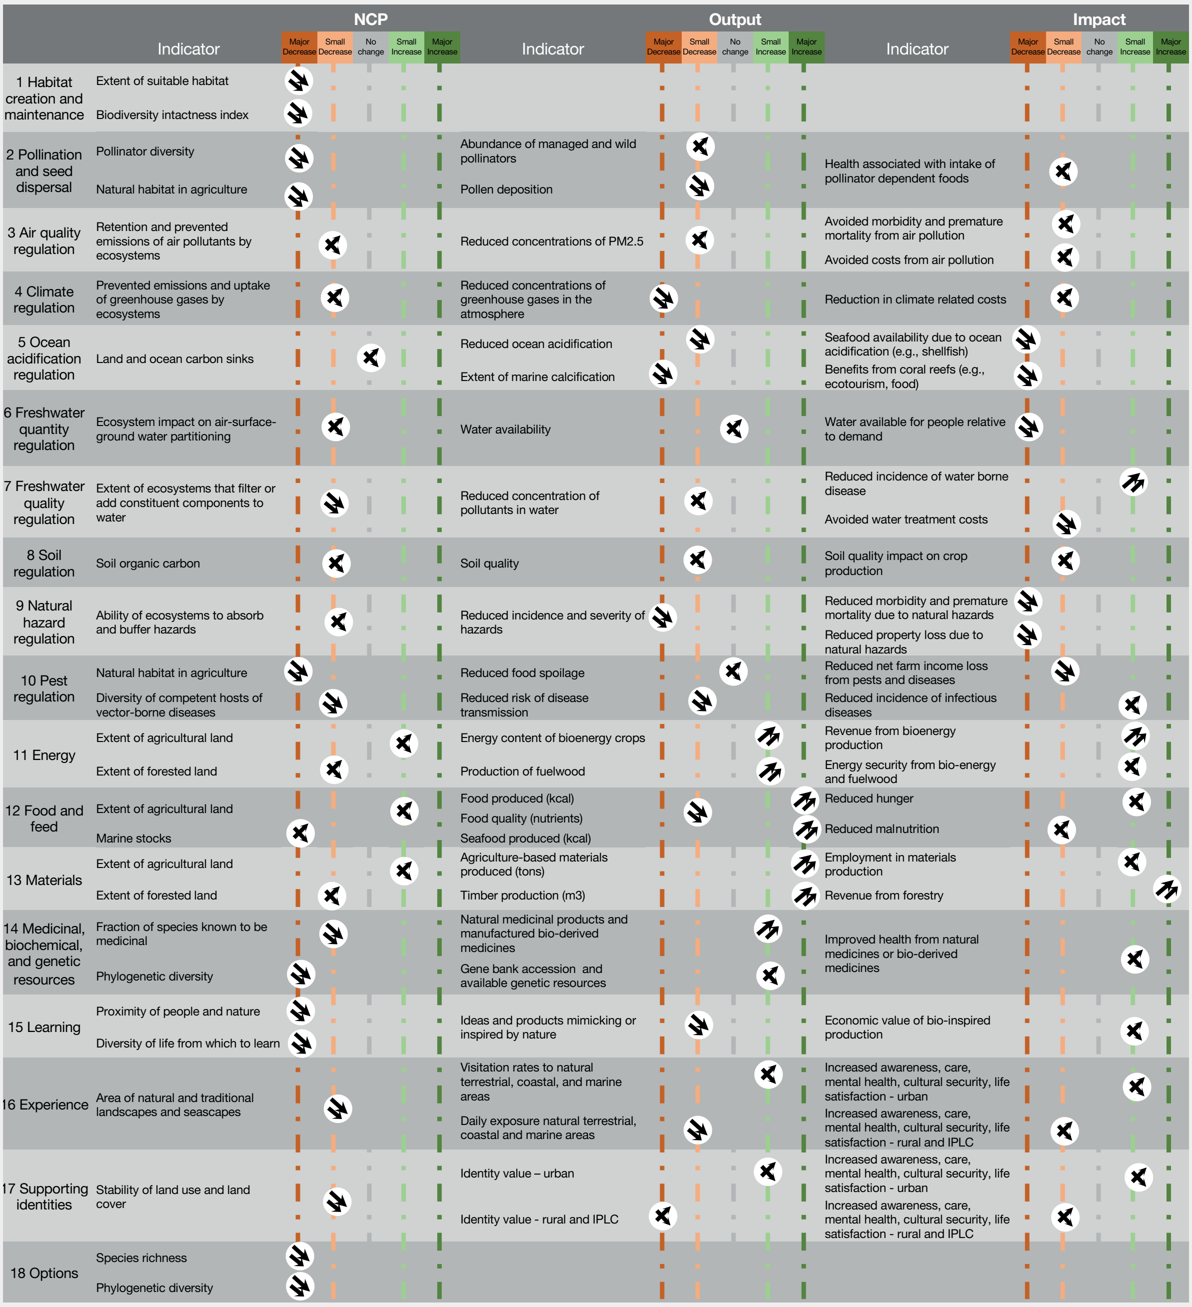

Figure 2 3 3 Global trends in potential NCP, output, and impact on good quality of life by 18 NCP.

For each NCP, the overall global trend over the past 50 years (1968-2018) for potential NCP (left panel), output (center panel), and impact on good quality of life (right panel) is indicated by a symbol and its location in columns indicating either major decrease, small decrease, no change, small increase, or major increase. When comprehensive data do not go back 50 years, trends are for a shorter period of time that match the length of data. Indicators are defined so that an increase in the indicator is associated with an improvement in NCP, output, or impact. Indicators related to harm or damage are thus defined as a reduction in harm or damage. Double arrows pointing either up or down indicate increasing or decreasing trends, respectively, across regions that are similar in direction but differ in magnitude. Crossed arrows indicate that trends in different regions show significant differences (e.g., declines in forests in most tropical regions and increases in forests in many temperate regions). Habitat creation and maintenance (NCP 1) and Maintenance of options (NCP 18) are both defined in terms of contributing to potential NCP and do not relate directly to output or impact on good quality of life.

Table 2 3 4 **Summary Evidence Base for Global Trends over the Past 50 Years by NCP.**

NCP	Potential	Output	Impact
1 – Habitat	Significant global habitat declines (Butchart *et al.,* 2010b) with differing magnitudes across regions. Well established.		
2 - Pollination	Global decrease in pollinator diversity (IPBES, 2016; Potts *et al.,* 2016; Regan *et al.,* 2015), most in industrialized regions, little evidence elsewhere (Bartomeus *et al.,* 2013; Biesmeijer *et al.,* 2006; Cameron *et al.,* 2011; Carvalheiro *et al.,* 2013; Koh *et al.,* 2016). Habitat destruction indicates decreases (Garibaldi *et al.,* 2011; Potts *et al.,* 2016). Well established.	Global decrease in pollinator abundance (IPBES, 2016; Potts *et al.,* 2016); indications of loss in pollination potential (Aizen & Harder, 2009; Garibaldi *et al.,* 2011; Koh *et al.,* 2016). Global deficits in crop pollination (Garibaldi *et al.,* 2016, 2011, 2013). Established but evidence is scattered.	Health impact from declines in animal pollinated-food via micronutrient deficiency (Smith *et al.,* 2015). Nutrition contribution from pollinator-dependent crops varies globally (Chaplin-Kramer *et al.,* 2014). Low income groups have less ability to compensate.
3 – Air Quality	Increase in air pollutants from biomass burning, deforestation, and agriculture, but increase in plant leaf area increases pollution retention and vegetation protects soils and prevents dust (Lelieveld *et al.,* 2015). Unresolved urban impact (Keeler *et al.,* 2019).	Global increase in emissions of fine particulate matter, black carbon, sulfur oxides, and ozone, but major regional variation (OECD, 2016). Well established by distributed monitoring networks.	3.3 million premature deaths annually attributed to air pollution (Amann *et al.,* 2013). Increasing trend in Asia and decreasing in US and Europe (Lelieveld *et al.,* 2015). Increasing cost of healthcare and lost work (OECD, 2016). Mixed impacts across user groups.
4 – Climate	Stable but spatially variable terrestrial sequestration in biomass and emissions from land use change, substantial interannual variation (Keenan *et al.,* 2015; Le Quéré *et al.,* 2018; Song *et al.,* 2018). Would be more sequestration with no anthropogenic land management (Erb *et al.,* 2018). Increase in methane and nitrous oxide emissions (Tian *et al.,* 2016). Precise contributions of ecosystems incomplete.	Greenhouse gas concentrations in the atmosphere have increased dramatically in the last 70 years (IPCC, 2014; Tarasova *et al.,* 2018). Well established.	Increase in economic cost of climate-driven extreme events leading to deaths, proliferation of diseases; agricultural disease outbreaks, and property damage (IPCC, 2014). Some regions have experienced improvement in agricultural production and fisheries (IPCC, 2014).
5 – Ocean Acidification	Stable terrestrial greenhouse gas emissions from land use change and sequestration in biomass (Le Quéré *et al.,* 2018). Increase in ocean carbon sequestration (Le Quéré *et al.,* 2018). Warming of upper ocean increases range of nitrogen-fixing phytoplankton, increasing ocean net primary productivity (Duarte, 2017; Morán *et al.,* 2010).	Ocean acidification has increased (IPCC, 2014) and marine calcification has dramatically declined (Kroeker *et al.,* 2010).	Decline in shellfish availability (Kroeker *et al.,* 2010). Increasing economic damage of coral reef loss, estimated to be US$500 to 870 billion by 2100 (Brander *et al.,* 2012).
6 – Water Quantity	Increased run-off quantity and flow speed due to deforestation, expanding (unirrigated) cropland, and urbanization (Sterling *et al.,* 2013; Trabucco *et al.,* 2008). Ecosystem change impact on water regulation established but incomplete (van Dijk & Keenan, 2007).	Global river discharge constant over past 50 years, but spatially variable (Haddeland *et al.,* 2014; Milliman *et al.,* 2008). Groundwater increases in some regions, decreased in others (Rodell *et al.,* 2018). Well established.	Increasing human water demand globally increasing water scarcity (Brauman *et al.,* 2016; Haddeland *et al.,* 2014). Regional variation but all are affected (WWAP, 2015). Impacts vary depending on adaptation capacity, but all are affected (WWAP, 2015). Direct linkages from water scarcity measures to impacts are inconclusive.
7 – Water Quality	Decreased filtration potential due to increased impervious surfaces and vegetation removal (Mayer *et al.,* 2007; Sweeney & Newbold, 2014), though varies globally (Seto *et al.,* 2012). Mechanisms well-understood but filtration effectiveness varies widely among studies (Mayer *et al.,* 2007; Sweeney & Newbold, 2014).	Global decrease in water quality; nutrient pollution and pathogens increasing and regionally variable trends in industrial waste (UNEP, 2016). Many local studies and some government reporting, but few globally consistent water quality measurements and indicators (UN Water, 2018).	Global decrease in the prevalence of water-borne disease, though at different rates (Prüss *et al.,* 2002; UNEP, 2016). Water-borne disease is well studied (WHO & UNICEF, 2017). Extent, quality, and spending on water treatment and sanitation increasing (WHO & UNICEF, 2017). Extent and expansion of infrastructure is well monitored (WHO & UNICEF, 2017).
8 – Soils	Global decline in soil organic carbon, regional variation (FAO & ITPS, 2015; IPBES, 2018a; Lal, 2015a, 2015b; Pierzynski & Brajendra, 2017).	Global decline in soil quality (FAO & ITPS, 2015; IPBES, 2018a; Lal, 2015a, 2015b; Pierzynski & Brajendra, 2017).	Declining crop yield due to soil degradation; regional variation (Bakker *et al.,* 2007; Lal & Moldenhauer, 1987; Sonneveld *et al.,* 2016). Variable capacity to compensate using substitutes like mineral fertilizer (Blanco-Canqui & Lal, 2008).

Table 2 3 4

NCP	Potential	Output	Impact
9 – Hazards	Decreased natural hazard regulation from land use change including shoreline hardening, floodplain development, and detrimental forest management (Renaud *et al.,* 2013). Most has reduced hazard regulation, but there have been positive changes (Arkema *et al.,* 2017; Renaud *et al.,* 2013). Mechanisms understood but poorly studied *in situ* (Renaud *et al.,* 2013).	Increasing number and magnitude of hazards (Guha-Sapir *et al.,* 2016; van Aalst, 2006). Number and location of disasters varies substantially year to year (Guha-Sapir *et al.,* 2016). Hazard occurrence is well studied (Guha-Sapir *et al.,* 2016).	Increasing number of people and value of impacted property (Guha-Sapir *et al.,* 2016). More impact with less robust institutions and on more vulnerable social groups (Kahn, 2005; United Nations Human Settlements Programme, 2003). Hazard occurrence and impact is well studied, but hazard regulation inconclusive (Guha-Sapir *et al.,* 2016; Renaud *et al.,* 2013).
10 – Pests	Decline of natural pest enemies and competent hosts of vector-borne and zoonotic diseases in all regions, with larger declines in the tropics and sub-tropics(Jones *et al.,* 2008). Decreased natural habitat in agriculture to support pest predators (Letourneau *et al.,* 2009).	Globally, food spoilage and crop loss due to pests has not changed significantly (Oerke, 2006). Risk of disease transmission has increased (Whitmee *et al.,* 2015).	Increased costs from decline in natural pest control (Oerke, 2006). Decrease in vector-borne disease incidence from 1950 to 1980 but increase in the last 30 years and is regionally variable (WHO, 2014). Established but incomplete.
11 – Energy	Increasing extent of agricultural land, though varies regionally (Alexandratos & Bruinsma, 2012). Global decrease in forested area to provide fuelwood, though varies regionally (Keenan *et al.,* 2015; Song *et al.,* 2018).	Increased energy production by biofuel crops (Koh & Ghazoul, 2008) and fuelwood (FAO, 2018a). Slow growth and some decline in traditional biomass, primarily for cooking and heating, with changing technology.	Increasing income from biomass energy (UNDP *et al.,* 2000). Biofuels key to household income (Cavendish, 2000; Dovie, 2003; Paumgarten & Shackleton, 2009; Rajagopal, 2008). Biomass energy, including timber and crop residues, provides energy security to more than two billion people (Schiermeier *et al.,* 2008).
12 – Food	Increase in harvested area, yields, and meat and milk production with regional variation (Alexandratos & Bruinsma, 2012). Decrease in fish catch potential (Cheung *et al.,* 2010), through variable across regions (Srinivasan *et al.,* 2010).	Increasing global production of food (Alexandratos & Bruinsma, 2012). Increased global fish catch and cultured (farmed) fish production (FAO, 2016). Current food production largely meets global caloric needs but fails to provide dietary diversity, notably fruits, nuts, and vegetables, for a healthy diet (Global Panel on Agriculture and Food Systems for Nutrition, 2016).	Decrease in hunger since 1970, though small increasing trend in past decade (FAO *et al.,* 2017). Malnutrition has increased since 1970, driven by increasing obesity, countered in many regions by decreasing undernutrition (FAO *et al.,* 2017).
13 – Materials	Increasing extent of agricultural land, though varies regionally (Alexandratos & Bruinsma, 2012), though area of cotton was stable. Global decline in forest area; much spatial variation (Keenan *et al.,* 2015; Song *et al.,* 2018).	Production of a majority of material resources has increased globally, though there is considerable diversity among materials (FAO, 2018b). Increased timber production (FAO, 2018a).	Globally, employment in forestry has probably increased since 1970 and reported employment has remained stable over the past 20 years (FAO, 2018b; Whiteman *et al.,* 2015). Increasing revenue from forestry (FAO, 2014).
14 – Medicine	Declining fraction of known medicinal species due to ILK decline, including access to customary territories; reduces capacity to identify new drugs from nature (Richerzhagen, 2010). Declining measures of phylogenetic diversity (Faith *et al.,* 2018).	Increase in medicines based on natural products (Newman & Cragg, 2012; Newman *et al.,* 2003). 30,000 new compounds from oceans (Alves *et al.,* 2018). Gene bank accession and genetic resources have increased (Tanksley & McCouch, 1997).	Increased health attributable to nature-based medicines; more than 50% of global population relies almost exclusively on natural medicines (Leaman, 2015; WHO, 2013).
15 – Learning	Declining population living in direct proximity to nature due to urbanization and migration (UN, 2014; WHO, 2016a). Reduced human-nature interactions (Soga & Gaston, 2016). Declining diversity of life from which to learn, measured as phylogenetic diversity (Faith *et al.,* 2018).	Global decrease in biodiversity in conjunction with fewer people living in proximity to nature leads to fewer ideas and products mimicking or inspired by nature (e.g., images of nature in children's media: Prévot-Julliard *et al.,* 2015; Williams *et al.,* 2012).	The overall value of bio-inspired goods is increasing, although it is concentrated within few very large industries (Richerzhagen, 2011).
16 - Experience	Declining area of natural and traditional landscapes and seascapes due to urbanization and land-use change (Seto *et al.,* 2011; Seto & Shepherd, 2009).	Nature visitation rates have risen in some areas and fallen in others (Balmford *et al.,* 2009, 2015). Daily exposure to nature has decreased as urbanization has increased (Soga & Gaston, 2016; Vining *et al.,* 2008).	Wealthy, urban interest in nature has increased (Keeler *et al.,* 2019), but rural migration and land use change have decreased well-being from nature exposure (Claval, 2005), particularly for the poor (United Nations Human Settlements Programme, 2003). Indications of positive mental and physical health impacts from exposure to nature, but findings are inconclusive (Bowler *et al.,* 2010; Daniel *et al.,* 2012).

Table 2 3 4

NCP	Potential	Output	Impact
17 – Identity	Stable human environments provide culture with the possibility to attribute value to it and form identities (Daniel *et al.,* 2012; Plieninger *et al.,* 2015a; Stephenson, 2008). Increased globalization, urbanization, and environmental degradation had decreased stability of land use and land cover (Milcu *et al.,* 2013; Plieninger *et al.,* 2015b).	In urban areas, increasing consciousness of nature and its contributions (Wood *et al.,* 2013). For rural and ILPC, decreasing local resource-based economies and loss of traditional knowledge and lifestyle and thus identities (Kaltenborn, 1998; Pascua *et al.,* 2017). Evidence of these connections is scattered.	Increasing youth interest in nature's contribution to identity (King & Church, 2013), and nature has become engrained in some national cultural identities, livelihoods, and national economies (Daniel *et al.,* 2012). Rural migration and land use change decrease identity linked to nature (Bell *et al.,* 2010; Claval, 2005; Daniel *et al.,* 2012).
18 - Options	Increasing species extinction rates; major regional variation (Ceballos *et al.,* 2017; Pimm *et al.,* 2014). Decreasing phylogenetic diversity (Faith *et al.,* 2018). Trends based on data but the places and species for high diversity loss are not well established.		

Trends in Outputs

The overall global trend in output has declined for 9 of 16 NCP. Output for all regulatory NCP (NCP 2-10), with the exception of water quantity (NCP 6), show a decline in output. As water cycles through the earth system, its volume remains relatively unchanged (NCP 6), although in some cases it has been redistributed, leading to regional variation. The decline in output for many regulatory NCP is related to the decline in potential NCP. For example, the decline in pollination by wild pollinators follows the decline in habitat for wild pollinators. However, for some regulatory NCP, increases in anthropogenic pollution emissions is the main cause of the decline in environmental quality (air quality – NCP 3, climate – NCP 4, and water quality – NCP 7). The atmospheric concentration of CO_2 – the major greenhouse gas – increased by 30% in the last 70 years (IPCC, 2014), driven by increased emissions. Much of the increase in GHG emissions from burning of fossil fuels has come from middle and high income countries, which is the dominant source of GHG emissions, while emissions from land-use change and reduced sequestration has come primarily from low income countries (IPCC, 2014; Pan *et al.,* 2011).

The production of material goods (energy - NCP 11, food and feed - NCP 12, and materials - NCP13) is increasing globally. The increase in production has come mostly from large-scale commercial enterprises. Global timber production has increased 48% relative to 1970 levels (FAO, 2018a). Some of the increases in material goods production, however, may not be sustainable. Overfishing has led to declines in many fish stocks because harvest has exceeded population replacement rates (Jackson *et al.,* 2001; Worm *et al.,* 2006). While fish harvests have increased over the past 50 years, many fish stocks have declined, which puts future fish harvests at risk. A similar pattern holds for medicinal, biochemical, and genetic resources (NCP 14), where the output of drugs, chemical compounds, and agro-seed industry, based on natural resources or mimicking the latter are increasing (Newman & Cragg, 2012), while phylogenetic and intra-specific diversity are decreasing, thus limiting options for the future (NCP 18).

Non-material NCP trends are varied and different indicators of non-material NCP show different trends. For example, there has been an increase in visitation to natural areas, suggesting an increase in experience of nature (NCP 16). However, more people live further removed from nature as the percentage of population living in dense urban areas continues to rise suggests that, for many, the experience of nature is declining. In contrast to material NCP, for which there are regularly reported global figures that summarize important trends in output, there is little agreement on what are the most appropriate measures of output, or regularly collected data with which to summarize global trends of non-material NCP.

Trends in Impact of NCP on Good Quality of Life

The overall global trend of impact of NCP on quality of life declined for 7 of 16 NCP, shows a mixed pattern for 6 NCP, and an unambiguous increase for 3 NCP. Changes in the impact of NCP on quality of life arise from changes in the co-production of NCP as well as from changes in factors more closely related to changes in institutions and anthropogenic assets, availability of substitutes, and human preferences. Increases in anthropogenic assets and human-made substitutes have offset the declines in potential NCP for some categories of NCP. For example, improvement in public health and sanitation measures have tended to reduce incidence of vector-borne diseases (NCP 10) even as potential NCP to regulate such diseases has declined.

The overall trends on impact on good quality of life across NCP are less negative than are the trends in potential NCP, in large part because of the interplay between changes in co-production and changes in social, economic, and political factors. The global trend for impact on good quality of life from material NCP (NCP 11-14) is positive, with the exception of reductions in malnutrition, from both under-nutrition and obesity (NCP 12). Nutrition problems do not arise from lack of ability to produce food. There has been a trend of rising calories per capita over the past 50 years (Alexandratos & Bruinsma, 2012; FAO, 2017b). Increasing agricultural production is largely due to increasing yields resulting from the use of modern varieties, increasing application of fertilizers and other inputs, as well as from expansion of the area in crop production (Alexandratos & Bruinsma, 2012; Foley *et al.*, 2011). With the global increase in food production, impact on malnutrition shows that the number of stunted children has decreased from 165.2 million in 2012 to 150.8 million in 2017, a 9 per cent decline (FAO *et al.*, 2018). Simultaneously, however, the prevalence of anemia among women of reproductive age, which has significant health and development consequences for both women and their children, has risen incrementally from 30.3 per cent in 2012 to 32.8 per cent in 2016, with no region showing a decline (FAO *et al.*, 2018)**.** Further, the unequal distribution of food means that there are over 800 million people suffering from hunger and malnutrition (FAO *et al.*, 2017), along with other nutrition problems arising from poor diets (Global Panel on Agriculture and Food Systems for Nutrition, 2016).

The overall trend for impact on good quality of life from regulatory NCP (NCP 2 – 10) is negative, with the exception of one indicator of water quality (NCP 7) and one indicator for pest regulation (NCP 10). These largely negative changes in the impact of NCP on good quality of life from regulatory NCP have been largely driven by declines in the co-production of NCP. For NCP 7, increased expenditure on water treatment has provided a substitute for decreases in water quality and the capacity of ecosystems to filter water, though poor water quality continues to have negative impacts on good quality of life.

Trade-offs among NCP

The pattern of increasing material NCP and declining regulatory NCP is largely a result of human management of ecosystems across the globe (MA, 2005; Rodríguez *et al.,* 2006; TEEB, 2010). NCP tend to come in bundles that depend on human actions such as land-use decisions and come with trade-off among different NCP (Raudsepp-Hearne *et al.,* 2010a; Rodríguez *et al.,* 2006). For example, land intensively managed for agriculture produces large amounts of energy (biofuels), food, or materials, but often at the cost of reducing natural vegetation and habitat for native species, carbon sequestration and storage, water quality, and other regulatory NCP (Bennett *et al.,* 2009; Polasky *et al.,* 2008; Smith *et al.,* 2012). Land-use and land management choices that are good for habitat preservation and biodiversity also tend to be good for many regulatory NCP (Chan *et al.,* 2006; Nelson *et al.,* 2009; Polasky *et al.,* 2012). However, even among synergistic NCP, there will rarely be perfect alignment. As a result, targeting for the provision of one NCP will typically mean that other NCP will not achieve their maximum potential outcome (Lawler *et al.,* 2014; Polasky *et al.,* 2012). Understanding the consequences of alternative land-use and land-management decisions, investing strategically in ecosystem restoration, and allocating land based on its contribution to multiple NCP, can generate simultaneous increases in the provision of multiple NCP (Bateman *et al.,* 2013; Lawler *et al.,* 2014; Ouyang *et al.,* 2016; Polasky *et al.,* 2008).

Decisions made in one location at one time can have impacts across many regions both now and into the future (Rodríguez *et al.,* 2006). Through international trade in commodities, there is virtual trade in carbon and water (e.g., Dalin *et al.,* 2012; Davis *et al.,* 2010; Hanasaki *et al.,* 2010; Liu *et al.,* 2017; MacDonald *et al.,* 2015; Peters *et al.,* 2012, 2011; Sato, 2014). Globalization and trade from distant demand can increase pressure on local ecosystems and on co-production of NCP (Chi *et al.,* 2017; Wolff *et al.,* 2017). Direct environmental linkages can also cause impacts across geographic regions and over time, as when there important impacts downwind (air quality regulation, NCP 3) or downstream (water quantity regulation, NCP 6, and water quality regulation, NCP 7), or through loss of habitat for migratory species (NCP 1).

2.3.5.2 Status by unit of analysis

For the vast majority of NCP, trends over the past 50 years in potential NCP, realized NCP, output, and impacts on good quality of life show significant differences by unit of analysis. In many cases, illustrated by crossing arrows in **Figure 2.3.3**, outputs move in different directions. For example, air quality, as measured by concentrations of PM2.5, has generally improved in high income countries over the past 50 years while it has declined, often significantly, in low and middle income countries over the past 50 year. For other NCP, trends are either downward or upward but differ significantly in magnitude, illustrated in **Figure 2.3.3** by two arrows in the same direction but with different length. For example, agricultural production has been generally increasing across the globe, but the extent of the increase varies widely across regions. In some cases, global greenhouse gas concentrations (NCP 4) and ocean acidification (NCP 5), effects are global and show similar patterns across units of analysis. NCP with strong consistent trends across biomes include air quality regulation (NCP 3), which is increasing as LAI increases globally (Zhu *et al.,* 2016), and soil (NCP 8), which has universally degraded from a pristine state (IPBES, 2018a; Stoorvogel *et al.,* 2017; Van der Esch *et al.,* 2017). Landscape cultivation for agriculture has occurred across all biomes **(Figure 2.3.4c)**, with the most agricultural land in temperate grassland and Mediterranean forest, followed by tropical forest, then temperate forest and grassland. Thus, as illustrated in **Figure 2.3.5**, potential for food production (NCP 12) is highest in temperate grassland. This is directly responsible for a decrease in potential for NCP that are more strongly related to intact habitat, such as habitat (NCP 1), options (NCP 18), pollination (NCP 2), pest regulation (NCP 10), and water quality regulation (NCP 7), which are lowest in the biomes in which agriculture is highest **(Figure 2.3.5)**. Because there is little conversion to agriculture in tundra, and to some extent drylands, these biomes have the lowest potential to produce food but the most potential to produce habitat-reliant NCP. Though food is both cultivated and wild-collected, we use cultivated area as a global indicator in **Figure 2.3.5** because the majority of global caloric production is cultivated.

Non-material NCP do not lend themselves to quantitative measures that can be assessed globally in the same way as regulating and material NCP. For Identity (NCP 17),

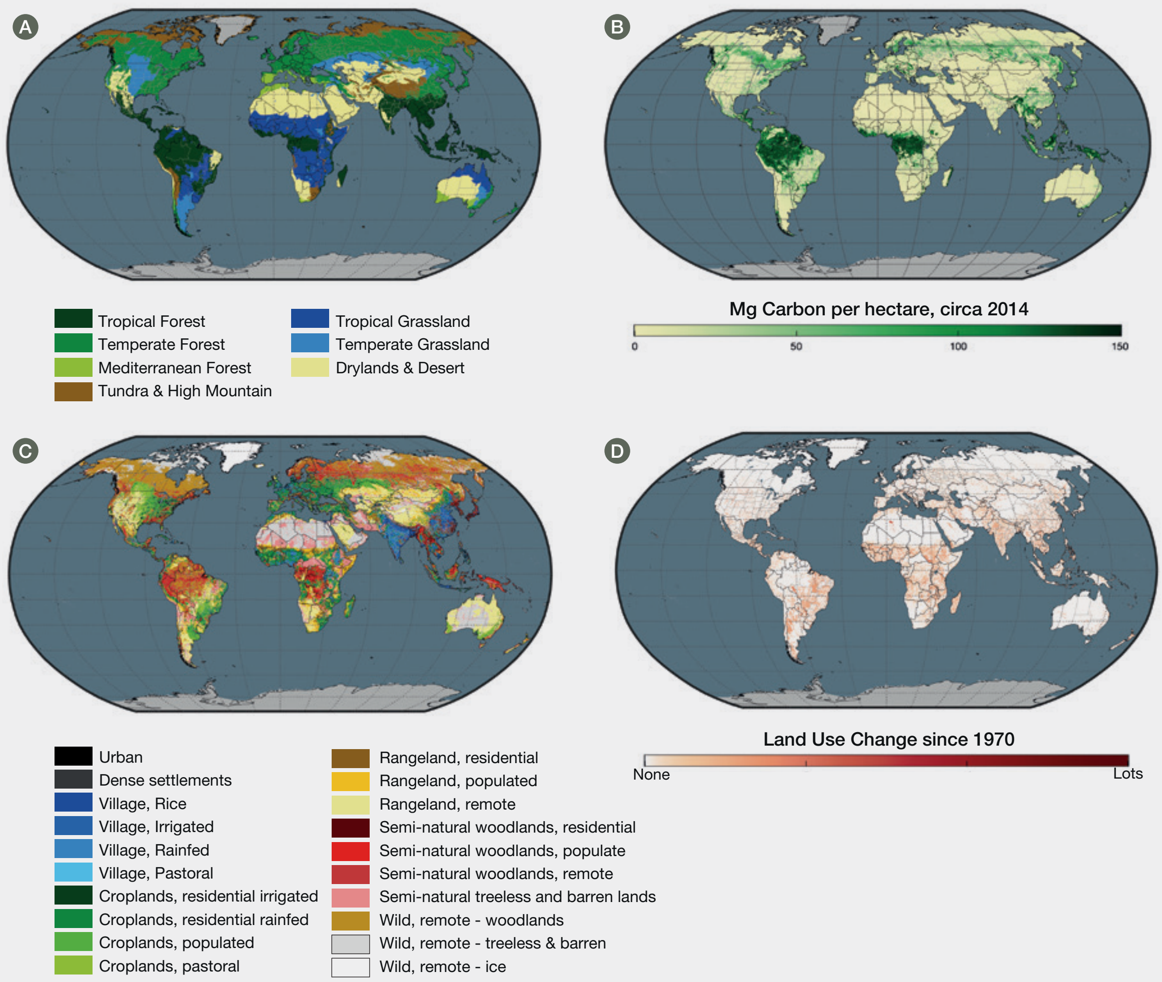

Figure 2 3 4 **Global Distribution of Selected Indicators Relevant to NCP.**

Across terrestrial biomes globally A, status and trends of NCP differ, yet some NCP co-vary. For example, biotic productivity is important for regulation of air (NCP 3), climate (NCP 4), and water quantity (NCP 6) and provision of energy (NCP 11) and materials (NCP 13); one indicator of biotic productivity is above ground biomass B. NCP that rely on relatively intact ecosystems, such as habitat (NCP 1), pollination (NCP 2), regulation of pests (NCP 10), and maintenance of options (NCP 18) have better status in places with more semi-natural and wild landcover C. Global land uses D. Land-use change since 1970 (high rates of land-use change was used as proxy for declining non-material NCP 17).

recognizing that abrupt changes in land use negatively affects identity (Antrop, 2005; Palang *et al.,* 2011), we use historic land use change since 1970 as an indicator **(Figure 2.3.4)**. Using a data proxy, we see that changes in tropical forest and grassland mean these biomes provide lower levels of identity NCP **(Figure 2.3.5)**. In many places, land use change was more dramatic between 1920 and 1970 than from 1970 to the present (Klein Goldewijk *et al.,*

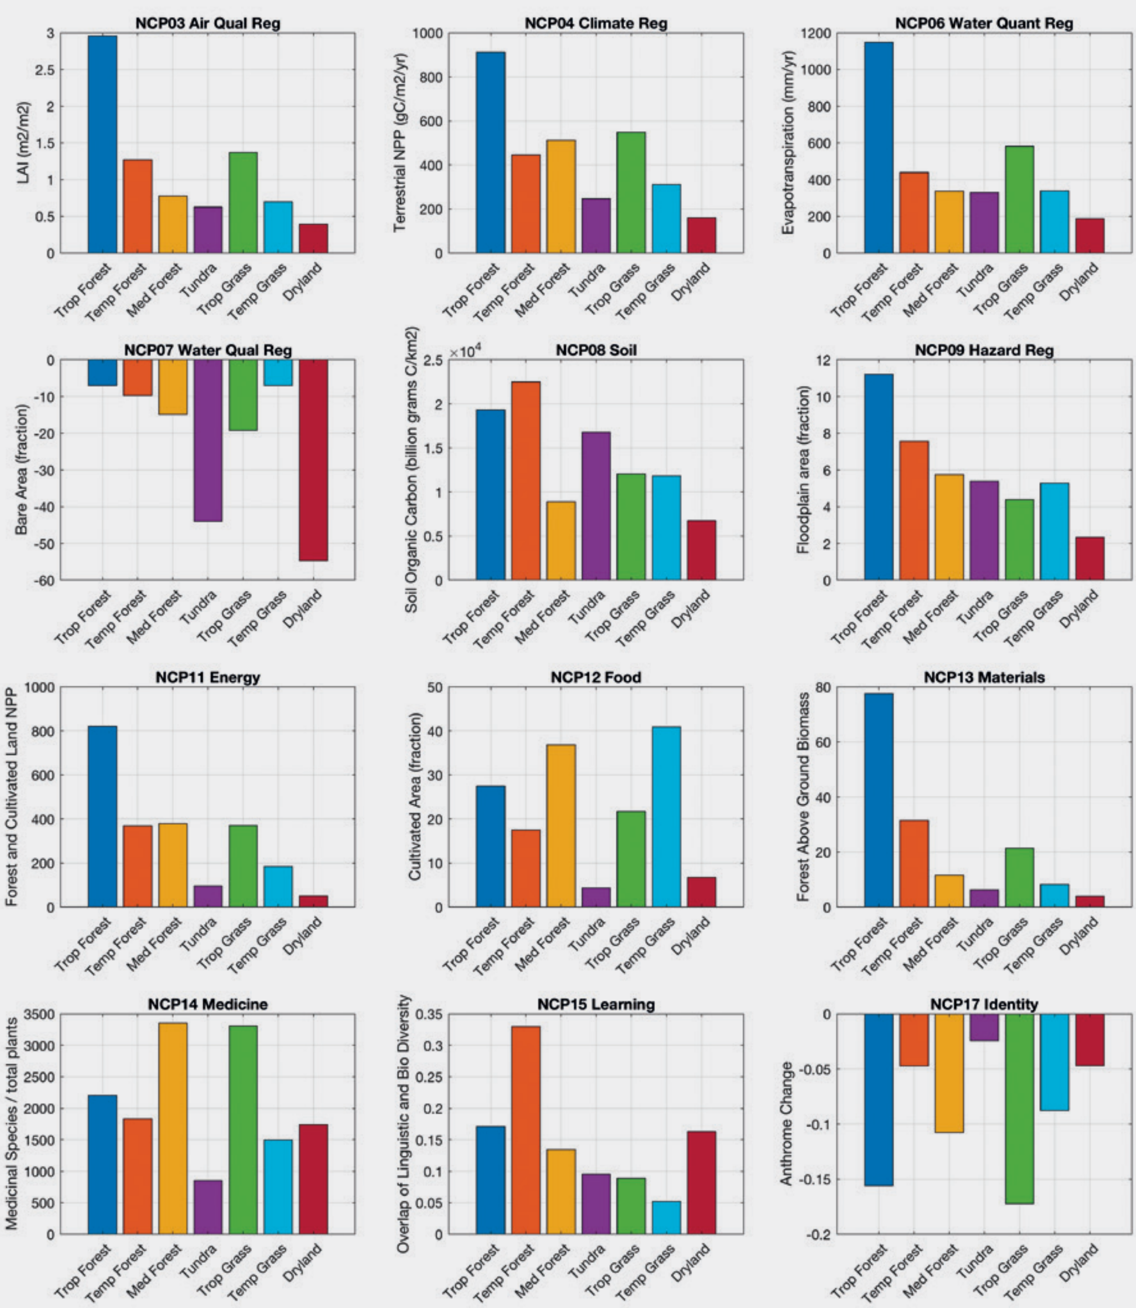

Figure 2 3 5 **Global Distribution of Data Proxies Relevant to Selected Potential NCP.**

NCP Status across biomes calculated using data proxies of the potential NCP indicators from **Figure 2.3.5**. Data were identified based on literature referenced in appendices and selected based on availability and alignment with subsection nature and other IPBES assessments. Few of the indicators proposed in previous research directly refer to existing datasets that are both global and spatially explicitly (de Groot *et al.*, 2010; Feld *et al.*, 2009; Hattam *et al.*, 2015; Heink *et al.*, 2016; Maes *et al.*, 2018; Pongratz *et al.*, 2018), but we aligned with these suggestions when possible. Average values were calculated for each data proxy over each biome. Data sources are listed in **Table 2.3.3**.

2017). For identity (NCP 17), the data proxy tells us there is plausibly a positive trend because potential NCP is less negative than it was in the preceding time period. Though current indicators and data proxies are weak, the help to recognize and track experience of nature in many all environments and over specific time periods.

Biotic productivity is a central component of many NCP. Both energy (NCP 11) and materials (NCP 13) are produced on agricultural lands, but fuelwood and timber make up a substantial fraction of total stocks, so we based indicators on biotic productivity. Similarly, air quality regulation (NCP 3), indicated by leaf surface area, climate regulation (NCP 3), indicated by net carbon sequestration, and water quantity regulation (NCP 6), indicated by transfer of water to the atmosphere, are very high in tropical forests, very low in tundra and drylands, and moderate in temperate and Mediterranean forest and grasslands **(Figure 2.3.5)**. Increasing biotic productivity means that, for most biomes, indicators of climate regulation (NCP 4), materials (NCP 13), and energy (NCP 11) are increasing. However, conversion of tropical forest **(Figure 2.3.4b, d, Figure 2.3.5)** counteracts this, leading to decreasing regulation of climate (NCP 4) and provision of energy (NCP 11) there.

Tropical forest, despite deforestation and downward trends for many NCP, continues to be incredibly important in providing for people. For most NCP, tropical forest is the biome with the highest potential for many NCP, including energy (NCP 11) and materials (NCP 13), as well as regulating services such as air (NCP 3), climate (NCP 4), and water distribution (NCP 6). Mediterranean forest and temperate grassland have the largest relative area converted to cultivated land, so while they are critical providers of food and feed (NCP 12), they provide lower levels of other NCP, particularly those linked to habitat intactness. Tropical grasslands have also been converted for food production, but because of their high biotic productivity **(Figure 2.3.4b)**, like tropical forests they continue to provide relatively high levels of NCP related to biotic production. By contrast, tundra and drylands have naturally lower levels of biotic productivity **(Figure 2.3.4b)** and so provide low levels of productivity-linked NCP, but as a result they have also had substantially less conversion for food production and so have relatively high levels of NCP provided by intact habitat. Co-production of medicine (NCP 14) is indicated by the fraction of vascular plants known to be medicinal, reflecting both biotic presence and human understanding; this is highest in Mediterranean forest and tropical grasslands.

The ocean provides many NCP, notably in meeting food (NCP 12) demand. Global annual per capita consumption of fish has more than doubled since 1960 (FAO, 2016), amounting to an annual increase of 3.2% in fish production for human consumption (UN, 2017). This increase has largely come from aquaculture, which has offset a decline in potential food production from marine fisheries: there was an 11% decline in biomass of assessed fish stocks in the wild between 1977 and 2009 (Worm *et al.,* 2009). Into the future, declines in wild-caught fish landings between 6 and 30% are predicted, depending on region, due to climate change (Cheung *et al.,* 2013). Other key provisioning NCP from oceans are materials (NCP 13) and medicines (NCP 14), both of which have been increasing over the past 50 years. The extraction of materials such as pearls, corals, marine ornamental organisms (pet trade), and shells has increased, particularly due to demand related to increased population and increased aquaria. In the case of marine-sourced medicines (NCP 14), 30,000 new marine medical compounds have been sourced from previously lesser known marine organisms in the last 50 years (Alves *et al.,* 2018). Innovative technologies in the fields of discovery and development of marine-based drugs hold much promise for a future increasing trend in NCP 14 (Montaser & Luesch, 2011).

Oceans also play a critical role in regulating ocean acidification through sequestration of carbon (NCP 5), regulating climate (NCP 4) and regulating natural hazards (NCP 9). For hazards, there has been a 13% decline in coastal protection since 1980, with serious consequences for damage by storms events and other natural disasters, which are increasing in frequency with climate change. In particular, destruction of mangrove forests through coastal degradation, and coral reefs through global warming and ocean acidification, is decreasing coastal protection, both due to reduction as a barrier to storm damage and also because carbon sequestration is declining (Heckbert *et al.*, 2012). For ocean acidification and climate, ocean net primary production, which has increased by around 6% globally between 1998 and 2007 (Behrenfeld *et al.*, 2006; Le Quéré *et al.*, 2018), is helping to mitigate the effects of global warming and ocean acidification through the uptake of CO_2 by marine primary producers. However, the detrimental effects of ocean acidification are reflected in shellfish availability, which has declined under ocean acidification as a result of the uptake of atmospheric CO_2 (Kroeker *et al.*, 2010).

The extensive three-dimensional nature of the oceans and their interactions with land and atmosphere alike (Hattam *et al.*, 2015) results in large spatial variability and uncertainties in the magnitude and even the directions of changes in NCP. However, what is clear is that maintaining healthy and diverse ocean ecosystems will be essential to sustain contributions of marine nature to people.

Freshwater systems get substantial attention for their contribution to food (NCP 12); freshwater fisheries are estimated to provide 40% of global fish production and be a particularly critical food and income resource for low income and subsistence fishers (Lynch *et al.,* 2016).

Within freshwater systems, water quantity regulation (NCP 6) occurs largely through the effects of vegetation on flow speed (Montakhab *et al.,* 2012) and on channel structure, which can in turn affect flow speed (Corenblit *et al.,* 2011). Freshwater systems are also critical for regulating water quality (NCP 7), as they account for about 20% of total global denitrification (Seitzinger *et al.,* 2006). Overall, in-stream processing has probably increased because nutrient loading has increased (Mulholland *et al.,* 2008). Freshwater systems are a net contributor to carbon emissions (Raymond *et al.,* 2013; Webb *et al.,* 2018). Freshwater systems also provide materials (NCP 13) such as mussels, historically used for buttons, and are key to learning (NCP 15), experience (NCP 16) and culture and identity (NCP 17) for many (Lynch *et al.,* 2016). However, freshwater biodiversity is declining rapidly and dramatically, suggesting that provision of many NCP from freshwater systems are declining and will continue to do so (Loh *et al.,* 2005).

Urban areas also provide many NCP, with green spaces such as parks, street trees, and riverbanks providing both regulating and non-material NCP, and a growing body of literature evaluates and assesses these NCP (Elmqvist *et al.,* 2013; Haase *et al.,* 2014; Hartig & Kahn Jr, 2016; Keeler *et al.,* 2019; Luederitz *et al.,* 2015). Trade-offs among NCP in urban areas are often strong: urban trees, for example, provide cooling (NCP 4) (Zardo *et al.,* 2017), stormwater control (NCP 6) (Berland *et al.,* 2017), and may improve mental health (NCP 16) (Keeler *et al.,* 2019), but also require substantial water resources (NCP 6) (Pataki *et al.,* 2011) and may be net contributors to air pollution (NCP 3) through volatile organic compounds and pollen (Janhäll, 2015). Though contact with nature may be decreasing overall, in urban areas there is an increasing demand for parks and green areas that are seen by many as supporting the identity of the town and its people (NCP 17), although there are many debates about the unequal access to green areas or parks by urban dwellers depending on wealth (Tang, 2017; Willemse, 2018). A global study on visitation of green areas and recreation parks shows that the highest demand for outdoor recreation in both rural and urban areas can be found in Canada, USA, Scandinavia, Spain, France, the Netherlands and Switzerland, given high levels of per-capita GDP and thus possibilities to participate in outdoor recreation (Wolff *et al.,* 2017). For water quality (NCP 7), for which increased urbanization and bare ground decrease provision, there is a decreasing trend.

Agricultural areas exhibit the diverse role of human interventions across regulating, material, and non-material NCP. Agroforestry management in the tropics, for example, can simultaneously maintain high levels of biodiversity while providing materials (NCP13), medicines (NCP 14), and learning processes for children (NCP 15) in addition to food production (NCP 12). IPLCs' practices of fresh water management (NCP 7) are illustrated in oases (Battesti, 2005), irrigated rice fields (Conklin, 1980; Settele, 1998), and cultivation on mounds in flooded inundated tropical savannas (McKey *et al.,* 2016, 2014). Contributions of generations of IPLCs to the selection, nurturing, and diversification of local animal landraces and plant varieties is widely recognized (Bellon *et al.,* 2017; FAO, 2007; Jarvis *et al.,* 2011), as is the design of non-industrial agroecosystems. Homegardens and agroforestry systems across the globe contribute to conservation and use of agricultural biodiversity. Diverse examples of IPLC contribution to the management and conservation of genetic resources include Soudano-Sahelian savannas and the large diversity of African cereals (Naino Jika *et al.,* 2017), taro horticulture in the pacific (Caillon *et al.,* 2006), and wild yam management by Pygmee hunter gatherers (Dounias, 1993). These practices are essential for not only the production of food and other directly consumed NCP, but also to maintain future options for the planet (NCP 18).

2.3.5.3 Status and Trends of Each NCP

NCP 1: Habitat Creation and Maintenance

Habitat continues to be in significant decline globally (chapter 2.2; Butchart *et al.,* 2010a). The extent of protected and intact habitat globally provides a critical indictor of NCP1. Many indicators of change in habitat quantity and quality exist, and these have been the subject of numerous reviews (e.g., Geijzendorffer *et al.,* 2016). Change in habitat quantity is best measured as the change in the extent of suitable habitat (ESH); measures of habitat quality in contrast benefit from including some measure of species composition. Recent evaluations have used the Biodiversity Intactness Index (BII) as a surrogate measure (Scholes & Biggs, 2005). ESH measures the extent of suitable habitat relative to a reference year whereas BII indicates the compositional intactness of local communities in comparison to an undisturbed state. It is unclear how much habitat creation and maintenance is required to provide NCP. Some have proposed habitat conservation targets of 50% (Dinerstein *et al.,* 2017; Hudson *et al.,* 2017; Wilson, 2016); 90% (ranging between 30–90%) has been proposed for BII (Steffen *et al.,* 2015). ESH and BII in combination speak to status and trends of habitat quantity and quality. In combination, these indicators suggest that only four biomes are above conservation thresholds: tundra, boreal forests/taiga, tropical and subtropical moist broadleaf forests, and mangroves (Hudson *et al.,* 2017). In contrast, Mediterranean habitats, temperate grasslands, and flooded grassland and savannas are well below either target and continue to decline. Chapter 2.2 discuses status and trends in nature in more detail. Many biomes, particularly those at high latitude, are under increasing threat and loss due to climate change and land use change. Mid-latitude biomes have experienced the greatest degree of habitat loss but are also where the greatest agricultural abandonment may be permitting some habitat restoration (Ramankutty *et al.,* 2008).

NCP 2: Pollination and Dispersal of Seeds

An extensive global review was recently performed by more than 77 scientists for the IPBES thematic assessment on pollinators, pollination, and food production (IPBES, 2016; Potts *et al.,* 2016). Declines in pollinator diversity have been recorded and are expected to continue globally. Currently, 16.5% of vertebrate pollinators are threatened with global extinction (IPBES, 2016; Potts *et al.,* 2016), and declines in bee diversity over the last century have been recorded in industrialized regions of the world, particularly northwestern Europe and eastern North America (Bartomeus *et al.,* 2013; Biesmeijer *et al.,* 2006; Cameron *et al.,* 2011; Carvalheiro *et al.,* 2013; Koh *et al.,* 2016). Evidence on the drivers of pollinator loss suggests a decline in pollinator diversity in Latin America, Africa, and Asia (Garibaldi *et al.,* 2011; IPBES, 2016). Propagule dispersal is also in decline globally. Currently, 26% of vertebrate seed dispersers are globally threatened (Aslan *et al.,* 2013). Species diversity reflects the potential of nature to provide pollination and dispersal services (Garibaldi *et al.,* 2013), while the abundance of organisms (both managed and wild) is used here as an indirect measure of the output (as well as pollen deposition). Usually, sites with more species diversity have also greater abundance (Garibaldi *et al.,* 2013).

These declines in animal pollinators could have significant negative consequences for the level and stability of pollination of crop and wild plants, and therefore good quality of life (IPBES, 2016; Potts *et al.,* 2016). Nearly 90% of wild flowering plant species depend, at least in part, on the transfer of pollen by animals. These wild plants critically contribute to most NCP. Moreover, the production of more than three quarters of the leading types of global food crops rely to some extent on animal pollination. An estimated 5–8% of global crop production would be lost without pollination services, representing US$235–577 billion annually on the basis of 2009 market prices and production (and inflated to 2015 US$) (IPBES, 2016; Potts *et al.,* 2016). Furthermore, changes in human diets and a disproportionate expansion of agricultural land are taking place to fill this shortfall in crop production by volume (Aizen *et al.,* 2009). Important global health burdens from both non-communicable diseases and micronutrient deficiencies are thus also expected due to pollinator loss (Smith *et al.,* 2015). Health impacts can be greater in areas with micronutrient deficiencies, such as Southeast Asia, where 50% of the production of plant-derived sources of vitamin A requires biotic pollination (Chaplin-Kramer *et al.,* 2014). However, these can be partially compensated by human choices of food and agricultural management. User groups vary greatly in their capacity to compensate the loss of pollinator-dependent food with other nutritious foods. Low income groups have less ability to compensate. It is unclear the degree to which humans can compensate for the loss of pollinator diversity.

NCP 3: Regulation of Air Quality

Air quality has declined globally as emissions of fine particulate matter, black carbon, nitrogen and sulfur oxides, and ozone have increased (OECD, 2016). Overall, increases in air pollution are higher in Asia, but reductions in air pollution have occurred in previously industrial regions of America and Europe. Globally, asthma and allergies resulting from air pollution have increased as well (Kim *et al.,* 2013). Nature contributes to regulation of air quality emissions by sequestering these emissions; it is well established that deforestation, biomass burning, and intensive agriculture release air pollutants (Lelieveld *et al.,* 2015). It is also well established that vegetation has the potential to prevent emissions by protecting soils to avoid air dust emissions and trapping some air pollutants in plant parts. There is also potential for nature to retain air pollutants on leafy surfaces, though the extent of this is probably small (Keeler *et al.,* 2019). Conversely, both flora and fauna frequently emit allergens, though more biodiverse species seem to reduce allergy intensity (Cariñanos & Casares-Porcel, 2011; Cresti & Linskens, 2000; Janhäll, 2015). Many of these functions are provided by well-developed vegetation structure, so nature's contribution to retaining and preventing emissions of air pollutants has been compromised through burning, deforestation, and agriculture (Lelieveld *et al.,* 2015). However, at a global level, leaf area has increased (Zhu *et al.,* 2013), so air quality regulation may be increasing. Assessment of air quality regulation by nature has usually been undertaken locally or nationally and has mostly been done in developed countries. Example findings of health benefits from air pollution retention by urban trees were $227.2 million Canadian dollars and $3.8 billion US dollars (Nowak *et al.,* 2006, 2018). In England, one study estimated net pollution absorption by woodlands reduced the deaths related to air pollution by 5–7% and hospital admissions by 4-6%, resulting is costs savings of £17,000–£900,000 (Powe & Willis, 2004).

NCP 4: Regulation of Climate

Atmospheric concentrations of CO_2 have increased by 30% in the last 70 years to levels unprecedented in the modern era, and other greenhouse gases have also increased (IPCC, 2014; WMO, 2017). This has large and negative consequences for humanity (IPCC, 2018). Ecosystems are both a sink and source of CO_2 and other greenhouse gasses (Le Quéré *et al.,* 2018). On land, ecosystems sequester carbon in vegetation and soils, and though there is substantial year-to-year variation, over the last 50 years terrestrial carbon sequestration has probably increased a small amount (Le Quéré *et al.,* 2018). In the oceans, biotic and abiotic processes sequester carbon, and this has also increased (Le Quéré *et al.,* 2018). Land-use change, especially deforestation, burning, and conversion to agriculture, is a major source of CO_2 emissions, nearly offsetting land-based sequestration (Le Quéré *et al.,* 2018). The world's forests are a major sink of CO_2 (Pan *et al.,* 2011), and nature's contribution to climate regulation decreases as forests are cut down and also used intensively (Erb *et al.,* 2018). These changes are not uniformly distributed across the global – global tree cover increased 7.2% from 1982–2016 (Song *et al.,* 2018), but the area of tropical forests – the terrestrial ecosystems with the largest carbon stocks – has declined (Keenan *et al.,* 2015; Song *et al.,* 2018). Overall, the contribution of tropical forests to the global carbon cycle has been, however, nearly neutral (Mitchard, 2018).

ILK is instrumental in maintaining sustainable environments and practices that contribute to climate regulation and its impact on good quality of life through (i) natural resources management, (ii) physical infrastructure, (iii) livelihood strategies, and (iv) social institutions. Reducing the pace and extent of land use change is one way that IPLCs contribute to maintaining nature's regulation of climate. The lifestyle and practices of IPLCs contribute to maintaining significant portions of ecologically intact landscapes globally. Indigenous lands, for instance, represent over a quarter of the world's land surface, including overlaping with near 40% of all terrestrial protected areas (see chapter 1 and 2.2; Garnett *et al.*, 2018). In addition, ILPC practices enhance climate regulation in many landscapes. Agroforestry as practiced by rural communities in South America (~3.2 million 3.2 million km^2), sub-Saharan Africa (1.9 million km^2), and Southeast Asia (1.3 million km^2), for example, maintains complex associations of carbon-storing plants and soils (Zomer *et al.*, 2009).

NCP 5: Regulation of Ocean Acidification

The ocean has the capacity to absorb CO_2 and thereby mitigate ocean acidification. In marine ecosystems, marshes, mangroves, and seagrass meadows take up CO_2 from seawater; carbon stored in these coastal environments is termed "blue carbon" which is locked into organic matter that can be preserved for a long time and may help offset ocean acidification locally. The ocean's regulation of acidification also includes assimilation of CO_2 by phytoplankton, as well as the capacity of seaweed aquaculture to affect pH and provide refugia for marine organisms with shells comprised of calcium carbonate (these organisms are termed calcifiers and include corals, crustaceans and several molluscs). Dense seaweed beds and kelp forests represent productivity hotspots with associated high pH when photosynthesis reduces CO_2 concentrations (Duarte, 2017). They may play a role in protecting calcifiers from projected ocean acidification. With warming of the upper ocean, the geographical range of nitrogen-fixing phytoplankton is likely to expand, so that net primary productivity may increase (although the phytoplankton community may be comprised of a larger proportion of small-celled phytoplankton) (Duarte, 2017; Morán *et al.,* 2010). Ocean acidification is especially problematic for corals and shellfish, because it prevents them from properly developing their skeletons and shells. Shell fish availability has declined under ocean acidification as a result of the uptake of atmospheric CO_2 (Kroeker *et al.,* 2010). Further, tropical coral reef ecosystems provide food, income, and coastal protection for around 500 million people throughout tropical coastal zones. The annual economic damage of ocean-acidification-induced coral reef loss by 2100 has been estimated to be US$500 to 870 billion depending on the level of CO_2 emissions scenarios (Brander *et al.,* 2012), and the corresponding global economic loss of shellfish production due to ocean acidification is estimated to be US$6-10 billion US$ per year (Narita *et al.,* 2012).

NCP 6: Regulation of Freshwater Quantity, Location, and Timing

Freshwater is critical for human well-being, and it is a limited resource distributed unevenly across the globe by natural and human-driven processes. Human demand for water is increasing worldwide, so water scarcity is increasing even when water availability does not change (Brauman *et al.,* 2016; Haddeland *et al.,* 2014). These impacts are unevenly distributed across social and user groups (WWAP, 2015). Nearly 75% of irrigated area and 50% of the population globally are sited in places where more than 75% of renewable water resources are consumed annually, seasonally, or in dry years (Brauman *et al.,* 2016). Changes in water availability are largely a result of changes in climate, evapotranspiration, and in human water extraction and river regulation (Milliman *et al.,* 2008). Ecosystems regulate freshwater by transferring water from the soil to the atmosphere, interacting directly with the atmosphere through processes such as cloud water interception and shading, developing flow paths from the ground surface through the soil, and physically interrupting the flow of surface water (Brauman *et al.,* 2007). The impact of land cover on water regulation occurs local and regionally through changes in evapotranspiration as well as locally via impacts on run-off (Beck *et al.,* 2013; Van Dijk *et al.,* 2009). In total, river discharge globally has remained constant over the past 50 years, though in about one third of rivers discharge has changed by more than 30% (Milliman *et al.,* 2008). Trends in groundwater vary significantly by region, with groundwater increases in areas of deforestation and cropland expansion (Rodell *et al.,* 2018). Global trends in deforestation, replacement of perennial vegetation with annual (un-irrigated) cropland, and urbanization have likely increased run-off quantity and also flow speed (Sterling *et al.,* 2013; Trabucco *et al.,* 2008). Modelling studies have been unable to unambiguously attribute large-scale measured changes in run-off and evapotranspiration to vegetation change (Haddeland *et al.,* 2014; Ukkola & Prentice, 2013).

NCP 7: Regulation of Freshwater Quality

Poor water quality is a critical source of illness in people, irrigation with saline water is a global threat to agricultural productivity, clean water is necessary for many types of manufacturing, and cultural and recreational enjoyment of water bodies is tightly linked to water quality (Prüss *et al.,* 2002). Though access to clean water is increasing and water-borne disease is decreasing, these trends are uneven across user groups (Ezzati *et al.,* 2002; WHO & UNICEF, 2017). Globally, water quality has decreased, though some regions show improved water quality (UNEP, 2016). Nutrient loading from anthropogenic sources, particularly agriculture and wastewater, has increased dramatically over the past 50 years, leading to increased eutrophication (Smith *et al.,* 2003; UNEP, 2016). Industrial water pollution has decreased in some regions but increased in others (UNEP, 2016). Nature can both contribute to and remove constituents in water. Ecosystems may provide direct additions of material to water, and through processing, uptake, and sequestration, they can also remove particles, pathogens, nutrients, and chemicals from water (Brauman *et al.,* 2007). Whether a change in water quality is considered beneficial depends on the suite of desired uses of water (Bernhardt, 2013; Keeler *et al.,* 2012). For example, mussels remove suspended solids, bacterial, and phytoplankton from the water column, which is frequently interpreted as a benefit, but invasive zebra mussels in North America do so to the extent that waters become very clear and cannot support fish or other aquatic life (Macisaac, 1996). The effectiveness of natural pollutant removal, such as through vegetated strips adjacent to waterways or in or wetlands, varies tremendously (Mayer *et al.,* 2007; Sweeney & Newbold, 2014).

NCP 8: Formation, Protection, and Decontamination of Soils

Soil degradation, particularly degradation caused by erosion, reduces crop productivity (Panagos *et al.,* 2018; Scherr, 2000), and the consequences are severe for low and middle income user groups who cannot compensate with anthropogenic substitutes (Blanco-Canqui & Lal, 2008). Land degradation has reduced agricultural productivity on 23% of global terrestrial area and affects 3.2 billion people (IPBES, 2018a). Nature contributes to better soil quality through improvement in soil biodiversity, mainly by enhancing soil organic carbon (SOC), which is a strong determinant of soil quality, soil health and crop productivity. SOC plays a crucial role in soil formation, soil protection, and other soil functions and derived benefits (FAO, 2017a; FAO & ITPS, 2015; Gaiser & Stahr, 2013). Globally, poor soil management practices have led to declines in soil carbon, biodiversity, and nutrients and to an increase in soil erosion, compaction, contamination, sealing, crusting and desertification, resulting in soil degradation and poor soil quality (FAO & ITPS, 2015; IPBES, 2018a; Lal, 2015a). The world has lost an estimated 8% of soil carbon globally due to land degradation, mostly because of agriculture (IPBES, 2018a; Sanderman *et al.,* 2017; Van der Esch *et al.,* 2017). These trends are not uniform globally, however; soil carbon stocks have improved in North America, for example, where widespread adoption of conservation agriculture (e.g., reduced tillage and improved residue management) has improved soil organic carbon stores on some cropland (FAO & ITPS, 2015; Lal, 2015b; Pierzynski & Brajendra, 2017). Despite discrepancies in country and regional estimates of soil organic carbon stocks (Hartemink *et al.,* 2010; Hengl *et al.,* 2017; Köchy *et al.,* 2015; Sanchez *et al.,* 2009), FAO (2017c) suggests that more than 60% of the 680 billion tonnes of carbon is found in ten countries: Russia, Canada, USA, China, Brazil, Indonesia, Australia, Argentina, Kazakhstan and Democratic Republic of Congo.

NCP 9: Regulation of Hazards and Extreme Events

Hazards, including fires, inland and coastal floods, and landslides, are increasing in both incidence and impact over time (Guha-Sapir *et al.,* 2016). While the number of disasters and people affected varies substantially year to year, close to 350 major disasters affecting close to 600 million people were reported in 2016, and the overall trend has been increasing over time (Guha-Sapir *et al.,* 2016). Changing drivers, including the risks of climate change and locations where people live, are increasing both the incidence and impacts of disasters (van Aalst, 2006). Hazards have a greater impact on more vulnerable social groups, and lower income countries and those with less robust institutions tend to be more affected by disasters (Kahn, 2005; United Nations Human Settlements Programme, 2003). Natural systems have the potential to reduce the incidence or impact of fire, floods, landslides, waves, and other destructive natural hazards. Nature and nature-based features can both increase and reduce disaster risk by increasing, preventing, or buffering the impacts of hazards and by changing people's exposure to hazards (Renaud *et al.,* 2013). For fires, floods, landslides, and coastal hazards, the physical structure of vegetation can serve a protective role by physically blocking hazards such as waves or rockfall, roots can help secure soils and sediments, stabilizing the abiotic elements of an ecosystem, and areas dedicated to natural ecosystems may physically displace people and structures that would be damaged by natural hazards. Ecosystems also help reduce hazards and their impacts by dissipating energy, moving water, and regulating fuel for fires. Nature-based approaches to disaster risk reduction are becoming increasingly appealing, but conversion of landscapes including shoreline hardening, floodplain development, and detrimental forest management that increases hazard impact remains widespread (Arkema *et al.,* 2017).

ILK enables some ILPC not only to anticipate, manage, and respond to natural hazards such as tsunamis (Lauer, 2012), cyclones (Paul & Routray, 2013), and heavy rains (Roncoli *et al.,* 2002). In many cases, responses to hazards reflect the magnitude of the perturbation. Papua New Guineans, for example, shift their farming practices in response to short-term frosts but engage in long-distance migration in response to long-term ones (Jacka, 2015). In addition, knowledge of wild or semi-domesticated plants provides survival foods in times of resource shortage (Yates & Anderson-Berry, 2004) (see Supplementary Materials, Appendix 1). The long-term transfer of knowledge, experiences, and practices related to disasters provides resilience to many IPLCs, though this is eroding in many areas experiencing cultural, inter-generational, and economic changes.

NCP 10: Regulation of Organisms Detrimental to Humans

Natural regulation of pests and pathogens improves food security, economic security, and human health. Weeds, animal pests, pathogens and viruses reduce production of food and cash crops worldwide. The absolute value of crop losses and overall proportion of crop losses have been steady over the past 40 years, fluctuating between 20–30% depending on crop and region (Oerke, 2006). Globally, chemical controls such as herbicides and pesticides have increased by 15–20% (Oerke, 2006), often substituting or replacing pest and disease regulating NCP co-produced by diversified cropping systems (within-field or alpha diversity) or cropping landscapes (between-field or beta diversity) (Tscharntke *et al.,* 2016). Vector-borne diseases infect more than 1 billion people per year, accounting for more than 17% of all infectious diseases, with more than 1 million deaths recorded from vector-borne diseases including malaria, dengue, schistosomiasis, leishmaniasis, Chagas disease, yellow fever, lymphatic filariasis and onchocerciasis (Karesh *et al.,* 2012). Trends in disease incidence are variable, with some diseases on the decline (malaria mortality -40% globally) but many more increasing (dengue +30-fold increase, Lyme disease currently the most common tick-borne disease globally) (Jones *et al.,* 2008; WHO, 2014). Climate change poses risks for crops and human disease, as habitat and infection ranges of crop pests (Bebber, 2013) and disease vectors (Kilpatrick & Randolph, 2012) expand. Loss of biodiversity could either increase or decrease disease transmission, though mounting evidence suggests that biodiversity loss increases disease transmission (Keesing *et al.,* 2010). Overall, despite many remaining questions, current evidence indicates that preserving intact ecosystems and their endemic biodiversity should generally reduce the prevalence of infectious diseases (Keesing *et al.,* 2010).

NCP 11: Energy

Bioenergy is renewable energy made from materials derived from biological sources. Biomass feedstocks are organic material that has stored energy from sunlight in the form of chemical energy and include plants, residues from agriculture or forestry, and the organic components of municipal and industrial wastes (Dale *et al.,* 2016). More than 2 billion people rely on wood fuel to meet their primary energy needs (Schiermeier *et al.,* 2008), and harvest and sale of biofuels often make up a a substantial portion of household income (Angelsen *et al.,* 2014). Use of biofuels, including biofuel crops (Koh & Ghazoul, 2008) and fuelwood (FAO, 2018b), is growing rapidly around the world. About 90% of bioenergy is consumed for traditional use – fires for household heating and cooking, but in recent years biomass has become a source of electricity, liquid fuel, and heat for towns and cities. It has been estimated that the world's generating capacity from biomass is at least 40 GW per year as of 2000 (UNDP *et al.,* 2000), and the extent of agricultural land on which bioenergy is produced is increasing (Alexandratos & Bruinsma, 2012).

NCP 12: Food and Feed

Globally, production of food is high and increasing, though the magnitude of these trends varies around the world. For agricultural crops, both harvested area and yields have increased, and meat and milk production have both increased over the past 50 years (Alexandratos & Bruinsma, 2012), yet meat and milk production have increased ten and sevenfold in Asia, while only 81% and 8% in Europe. Global fish catches increased by around 50% over the last 50 years, and cultured (farmed) fish production escalated from insignificant fractions of wild catch to comprise ~40% of total seafood production in 2015 (FAO, 2016). In the last ten years, wild fish catch declined by 10% whereas farmed fish/seafood increased by 20% (FAO, 2016; Worm *et al.,* 2009). Fish catch potential is expected to vary in both magnitude and direction depending on temperature, oxygen and pH changes, which are projected to be different in different parts of the globe (Cheung *et al.,* 2016).

Despite these increases in production, the potential of nature to sustainably contribute to food production is declining. Land degradation has reduced agricultural productivity on 23% of global terrestrial area and affects 3.2 billion people (IPBES, 2018a). All taxa of wild crop relatives have decreased, with an estimated 16–22% of species predicted to go extinct and most species losing over 50% of their range size (Jarvis *et al.*, 2008). Similarly, fish catch potential, a measure of fisheries productivity as a function of primary production and distribution of fish and invertebrates (Cheung *et al.*, 2010), is variable across areas but has decreased substantially, with 7–36% loss in catches estimated for 2000 due to overfishing (Srinivasan *et al.*, 2010), and there is little scope for expanding fisheries into the future (FAO, 2016).

The impact of these trends in output as well as potential NCP on quality of life is variable. While current food production could largely meet global caloric needs, unequal distribution of calorie uptake among regions, high levels of food waste, and intensive production of a limited number of crops in large quantities (cereals, starchy root crops, meat and dairy, oilseeds, and sugar) mean that malnutrition remains prevalent. Hunger has decreased globally since 1970, though there are still over 800 million people facing chronic food deprivation and those numbers have increased slightly in the past decade (FAO *et al.,* 2017, 2018). The prevalence of undernourishment is highest and worsening in many regions of Africa, affecting almost 21% of the population (more than 256 million people); The prevalence of undernourishment is estimated to be 5% in South America and 11% in Asia (FAO *et al.,* 2017, 2018). Malnutrition has increased since 1970, driven by increasing obesity, countered in many regions by decreasing undernutrition (FAO *et al.,* 2017, 2018). National food supplies worldwide are now more similar in composition than previously, leading to the establishment of a global standard food supply, which is relatively species-rich in regard to measured crops at the national level, but species-poor globally (Herrero *et al.,* 2017; Khoury *et al.,* 2014). Dietary diversity, notably in fruits, nuts, and vegetables, required in a low health risk diet (Global Panel on Agriculture and Food Systems for Nutrition, 2016; Johns *et al.,* 2013; Powell *et al.,* 2015). Food production systems that integrate more diversity and less chemical inputs such as agroforestry systems could improve diversified diets and reduce impacts on climate, soil, water quality, and habitat (Springmann *et al.,* 2018). For fishers, demand for fish resources is increasing, likely with reduced benefits in terms of livelihood per fisher (McCluskey & Lewison, 2008; Worm *et al.,* 2009).

NCP 13: Materials and Assistance

The production of a majority of material resources has increased globally since 1970, though there is considerable diversity among them. The production of materials extracted from forest ecosystems such as timber (round wood production), natural gums, and resins has increased since 1970 (FAO, 2018a). Likewise, production has increased of a majority of fibre crops derived from agroecosystems such as cotton, agave, coir, and silk; production of some other fibers has decreased (hemp, sisal, bastfibres) or remained relatively constant (jute, manila) (FAO, 2018a). Although cotton growing area has remained constant, cotton production has nearly doubled since 1961 due to improved seed varieties, irrigation, and the use of pesticides and herbicides (Cotton Australia, 2016). For many materials, the trend in recent decades has been towards more heavily managed systems. For example, timber is increasingly harvested from forest plantations, traded wildlife such as birds, reptiles, and aquarium fish are increasingly produced in captivity, and most of the traded ornamental plants, including orchids, are now produced in cultivated systems. Trends in provision of different material resources vary around the world. Forest plantations have increased in boreal regions, Central America, South America, and South and Southeast Asia (Keenan *et al.*, 2015). Collection of materials can decrease the potential for provision over the long term. For example, one cause of coral reef degradation is extraction for aquarium use (Jackson *et al.*, 2001).

Materials impact quality life by providing shelter, providing raw materials for many industries such as textiles, furniture, and crafts, are sources of inspiration, and create employment and provide income. Globally, total employment in the forestry sector was about 13.2 million in 2011, a decline of about six per cent from 2000 (FAO, 2014). Trends in forestry employment vary across regions. Western and Eastern Europe, North America, and the developed Asia Pacific region have seen major declines in forestry sector jobs, due in part to the global economic crisis in 2008–2009, replacement of manual work with machinery (Europe, Australia, New Zealand), increasing import of furniture from the other regions (North America), and decreasing production (Japan) (FAO, 2014). Other regions, however, have increased forestry employment. Developing Asia-Pacific, Latin America and the Caribbean, North Africa, and Western and Central Asia combined created 1.1 million new jobs between 2000 and 2011 (FAO, 2014). This increase occurred mainly in China, India, Vietnam, and Thailand as wood processing and pulp and paper industries expanded rapidly, primarily for export. Employment in the global textile industries, including cotton cultivation, is increasing.

NCP 14: Medicinal, Biochemical, and Genetic Resources

Materials derived from organisms (plants, animals, fungi, microbes) for medicinal and veterinary purposes contribute to health, income, and cultural development, medical systems being a set of culture associated with a range of relational values (MA, 2005). These products represent full organisms, portions of organisms, and genetic resources including genetic information (Richerzhagen, 2010). Identifying natural products and transforming them into Natural Medicinal Products (NMPs) depends both on human capacity to identify species and link them to specific illnesses and the availability and quality of these species.

Box 2 3 2 **Caterpillar Fungus, an example of NCP 13 Materials.**

Known popularly as 'Himalayan Viagra,' the caterpillar fungus *(Ophiocordyceps sinensis)* is the world's most expensive biological commodity (Shrestha and Bawa, 2013). Used in traditional Chinese medicine and recently embraced as an aphrodisiac and a powerful tonic to enhance libido, the caterpillar fungus is found only in high-elevation pastures in the Himalayas and Tibetan plateau. It is an endo-parasitic complex formed when the pathogenic fungus parasitizes the caterpillars of ghost moths (Hepialidae) found above 3500m. The tiny 2-6-inch-long fruiting bodies, each weighing less than a half gram, are harvested by hundreds of thousands of mountain dwellers in China, India, Nepal, and Bhutan every year from May to July (Shrestha and Bawa, 2013).

Harvest and sale of the caterpillar fungus supports poverty-stricken local people, accounting for more than 70% of many people's total income (Shrestha and Bawa 2014). However, though the fungus has brought economic prosperity to regions where livelihood options are limited, its harvest has created social and environmental problems. Unsustainable over-harvest and climate change have reduced the number of caterpillar fungus collected each year, leading to conflict between communities over resource rights (Hopping *et al.,* 2018). Increased collection effort has sent more people further afield, degrading grassland habitats. In response, collection and trade of caterpillar fungus has been banned in India and regulated in Nepal and Bhutan yet harvest and trade into the multi-billion dollar international market as continued unabated. Photo: Uttam Babu Shrestha.

Tens of thousands of medicinal plants are used (Hamilton, 2004; Leaman, 2015; Schippmann *et al.,* 2006). Globally, more than 25% of new drugs are derived from natural products, with more than 70% of drugs to treat cancers derived directly from natural medicinal products (Newman & Cragg, 2012; Newman *et al.,* 2003). More than 20% of modern drugs used for all diseases globally are based on leads from natural molecules, identified by science or based on ILK; these include aspirin, vincristine, and taxol. The search for new medicines has concentrated in plants; 70,000 medicinal plants species, about 17% of the world known flora, are estimated to be used at the global level (Schippmann *et al.,* 2006 - IUCN Medicinal Plants Specialist Group). There are 656 flowering plant species used to treat diabetes (Allkin *et al.,* 2017), which affects an estimated 422 million adults. In addition, terrestrial animals, fungi and ocean biodiversity have potential to provide medicinal resources, but few taxa have been tested or explored thoroughly (Colwell, 2002). Over the last 50 years, more than 30,000 new compounds and more than 300 patents have been derived from marine species (Alves *et al.,* 2018). Similar patterns are known for fungi, based on existing Asiatic pharmacopeia, which has been little studied to date. Certain taxa have proven to be more likely to have useful compounds. ILK or scientific screening approaches use taxonomic cues and concentrate their efforts in specific biota to identify natural medicinal products (Saslis-Lagoudakis *et al.,* 2014, 2012).

Though discovery and use of new drugs and compounds based on nature has increased (Newman & Cragg, 2012; Newman *et al.*, 2003), this is largely due to advances in techniques over the last 30 years as well as major discoveries in new areas of investigation such as marine products or fungi (Alves *et al.*, 2018; Newman & Cragg, 2012). Declines in biodiversity mean we are losing genetic resources, with consequent loss in the potential for new discovery of drugs and biochemical compounds (Richerzhagen, 2010). It is estimated that 21% of known medicinal plants are threatened (Schippmann *et al.*, 2006). Loss of knowledge, especially traditional orally-transmitted pharmacopeia, also threaten the potential to identify new medicines (Aswani *et al.*, 2018). The intersection of global plant richness (Kreft & Jetz, 2007) with known plant medicinal species (RGB Kew, 2016) is an indicator showing areas with differential potential across units of analysis and ecosystems.

The impact of natural medicinal resources on quality of life includes direct impacts on health as well as income generated by traditional medicine production and the pharmaceutical industry. It is estimated that 70–80% of people worldwide rely chiefly on traditional, largely herbal medicine to meet their primary healthcare needs (Farnsworth & Soejarto, 1991; Hamilton, 2004). In 2003, the WHO estimated the annual global market for herbal medicines to be worth US$60 billion, and by 2012 the global industry in Traditional Chinese Medicine alone was reported to be worth US$83 billion (Allkin *et al.,* 2017). In 2006, the pharmaceutical market comprised US$ 640 billion, with 25–50% of the products derived from genetic resources; it is estimated that the pharmaceutical industry earns about US$32 billion a year in profits from products derived from traditional remedies (Richerzhagen, 2010, 2011). The agricultural seed market's value was US$30 billion in 2006, and all of its products are derived from genetic resources from nature (ten Brink *et al.,* 2011).

NCP 15: Learning and Inspiration

Proximity to nature enhances learning processes, and the richness of nature is the basis of learning processes including subsistence, science, art, and ensuring humanity's basic and non-material needs (material protection, food, health, communication, culture, religion etc.) (Descola, 2013; Ellen, 2002; Kuo *et al.,* 2019). Direct sensorial experiences with nature are critical to learning and ensuring psychological health (Cox *et al.,* 2017; Dounias & Aumeeruddy-Thomas, 2017). An indicator of nature's importance to learning is shown by the correlation between high cultural diversity and areas of high biodiversity (IPBES, 2018a; Maffi, 2002; Stepp *et al.,* 2004). Mimicry of nature is the origin of many scientific findings: chemical dyes and colors (Nieto-Galan, 2007), bio-inspired medicines (Newman & Cragg, 2012), and sustainable bio-materials (Hunter, 2017). Patterns in nature also inspire thinking processes, such as phylogenetic trees (Hinchliff *et al.,* 2015). Across all cultures, nature is symbolized within paintings, engravings, sculptures, theatre, dancing, language, and other forms of artistic or cultural expression (Cohen, 2005; Fernández-Giménez, 2015; Hunter, 2017).

Learning from nature is declining due to both overall loss of species richness, evidenced by loss of ethnoecological knowledge of nature, and changes in lifestyles (Aswani *et al.,* 2018). Urbanization decreases proximity with nature and tends to change the forms of relationships between people and nature. More than 50% of the global population now lives in urban areas, far from relatively natural areas or biodiversity rich landscapes. Lack of proximity to nature decreases knowledge, especially ILK critical to identification of natural medicinal products. Learning processes are likely to decrease with a global decrease in ILK (Aswani *et al.,* 2018), and global capacity to learn from ILK is therefore likely to decrease. Declines in nature-based learning may be particularly acute in agrodiversity and medicine, where traditional selection of crops and identification of natural medicines have derived initially from ILK. Learning about food-related genetic resources, of which the vast majority are found in traditional agroecosystems such as shifting cultivation, is declining as industrial monocultural plantations increase (Heinimann *et al.,* 2017). There is a significant loss of representation of nature in art and an increase in fragmented use of nature in science that is often disconnected from natural processes. Declines in nature-based learning are not universal, however; some sub-populations increase learning by travelling to natural areas for recreation (Wolff *et al.,* 2017) and by accessing nature through books, television, and the Internet. The digital age is likely to facilitate new connections between nature and culture (Ithurbide & Rivron, 2017; Liang, 2009).

Humankind learns from nature, experiments and learns from natural processes, and uses ecological traits to select crops, medicines for healing, and produce materials. Learning to modify nature for the benefit of humankind is one of the major principles of learning. This type of learning is the basis of humankind's capacity to transform natural processes and thereby replace many of the benefits of nature, such as the development of chemicals to replace soil fertility. This kind of transformative learning also allows people to change the composition of nature through genetic modification. As a result, science is increasingly using information from nature and then mimicking nature, for example using abstract equations or fractals to access elements of nature or using nanotechnologies to develop biomimicry (Hunter, 2017), leading to a slight decrease in the use of nature

Box 2 3 3 **Learning and Experiences: Why proximity to nature matters to our children .**

Nature matters to children. Natural environments provide developmental benefits for children and promote creativity, exploration, divergent thinking that can aid recovery from stress (Wells & Evans, 2003; cited by Sargisson & McLean, 2012), and cognitive restoration. Children report a desire for more trees and green spaces in their schools (Sargisson & McLean, 2012). Throughout the world and in all societies, children are known to observe nature differently than adults (Dounias & Aumeeruddy-Thomas, 2017), to access spaces in nature that adults do not use, such as climbing on trees, and to do this even in landscapes where very little nature remains. Children establish analogies between human worlds and non-human worlds by creating special linkages with nature through their imagination (Simenel, 2017). Children's access to nature can follow very different rules in different societies; this was observed in Indonesian agroforestry systems where private agroforests can only be accessed by their owners yet children from all village families are allowed to transgress such rules, given them special access to wild fruits of different kinds never eaten by adults (Aumeeruddy-Thomas, 1994).

Children give particular attention to some taxa for which adults do not care. As shown by Simenel *et al.* (2017):

"Playing with insects is probably a constant and almost universal element in the history of human childhoods. The universal character of the recreational appeal of insects for children lies in two of their characteristics: first, the diversity of their forms and behaviors, however bizarre they may at first appear to young humans, never fail to stimulate their imaginations, and second, their small size is the basis on which many cultures draw analogies to the small size of children. Costa Neto (2003) notes in his work in Brazil that most children in rural areas play with insects. Similarly, whilst it is adults who indulge in cricket fighting activities in Indonesia, it is highly likely that children are involved in finding and collecting the crickets (Pemberton, 2003). These few observations raise important questions regarding the autonomous learning processes resulting from encounters between children and insects and the way in which these processes are incorporated into the acquisition of skills linked to adult activities."

In Southern Morocco, Simenel *et al.* (2017) show that beekeeping is a very important activity but that children are not allowed to manipulate beehives until they are late adolescents and must follow and observe the activities of their fathers. Due to these restrictions, children have developed a whole set of activities with solitary bees (a variety of species of the Megachilidae family) with whom they play, who they consider as their friends, and whose stores of pollen they collect and eat or sell to other children. These small solitary bees store their pollen in small empty shells of snails. Children's games involving solitary bees nurtures their fondness for beekeeping, a risky activity that they cannot yet afford to practice and can only observe through accompanying adult beekeepers. This example demonstrates that learning about the role of pollinators can start very early in childhood and that children are probably a key subset of all user groups at global level and in many biomes that develop their interest in nurturing and protecting plant-insects-human relationships.

and natural processes by science. Learning to transform nature has had both positive and negative impacts on quality of life. Genetically modified organisms, for example, have immediate positive impacts on the production of food and raw materials, but issues are arising about potential negative impacts on the environment (Pott *et al.,* 2018). Similarly, the use of gene drive techniques on mosquitoes, although not yet released *in situ*, are expected to have major benefits for human health (Hammond *et al.,* 2017), but such approaches are under debate due to ethical and environmental concerns.

NCP 16: Physical and Psychological Experiences

There are long held beliefs that human health and well-being are influenced positively by spending time in natural settings, and beneficial properties are attributed to activities in nature (Bishop, 2012; Stigsdotter *et al.,* 2011). Exposure in to nature in urban settings and is also thought to improve mental health, though reviews of scientific findings have been inconclusive about the extent of this effect and the elements of nature which might provide it (Gascon *et al.,* 2015; Lee & Maheswaran, 2011). Reflecting a growing recognition of the value of nature and cultural resources, the number and extent of protected areas established globally has increased. Over 30 million square kilometers have been protected in the last 50 years and the number of protected areas designated and/or recognized by countries has doubled every decade for the last 20 years (Deguinet *et al.,* 2014). Visitation to these protected areas has also increased. The world's terrestrial protected areas receive roughly 8 billion visits each year, more than 80% by European and North American visitors (Balmford *et al.,* 2015). These visits are estimated to generate approximately US $600 billion per year in direct in-country expenditure (Balmford *et al.,* 2015). Experience of nature has also been modified and popularized through the spa industry, mineral and natural springs, human-made gardens and forests, and many others (Erfurt-Cooper, 2010; Erfurt-Cooper & Cooper, 2009). This is one way of servicing the needs of the growing appetite for the experience of nature among affluent urban dwellers in the years to come. The establishment of protected areas, national parks, and tourist amenities such as spas are not always beneficial for traditional peoples whose lives are intertwined with nature (Laltaika & Askew, 2018). Protected areas and national parks can impoverish people and ultimately dispossess them from their homes and ultimately lead to the loss of ILK.

NCP 17: Supporting Identities

Nature provides culture with the possibility to attribute value to it, and culture attributes value to nature. The abundance of natural ecosystems, especially those with continued existence over longer periods of time, could be seen as a prerequisite for supporting identities. However, without culture this remains a potential only. Non-material and spiritual values are part of people's cultures and play a crucial role in shaping their perception of nature (Verschuuren *et al.,* 2010). In many cases identity is inseparably linked to a particular place or resource (such as Indigenous Peoples of the North and of the Pacific Islands). In these places, local economies depend strongly on the availability of natural resources, but also on cultural knowledge, traditionally transmitted from generation to generation, regarding the ways of preparation, storage, and distribution of food and resources (e.g., Kaltenborn, 1998; Pascua *et al.,* 2017). With increased globalization, urbanization, and environmental degradation these identities are at risk. Loss of identity has a direct impact on quality of life and human well-being and could result in health problems such as depression, alcoholism, suicide, and violence (Kirmayer *et al.,* 2011) and loss of security (IPBES, 2018b; Pascua *et al.,* 2017). At the same time, there seems to be an increasing awareness about cultural values, traditions, and environmental conservation, especially by urbanized and wealthy people who have otherwise become more distant from nature. High identity value results in better social cohesion, stronger sense of place, spiritual and cultural well-being, and thereby better care for the environment. Spiritual and religious values can be instrumental in promoting biodiversity conservation (Chan *et al.,* 2016; Daniel *et al.,* 2012; Hernández-Morcillo *et al.,* 2013), although there remains some risk for underestimating the complexities of lived experiences of spirituality and religiosity. Attempts have been made to use sacred areas as a point of departure when creating protected areas. There are important signs that youth, at least in the US, but also elsewhere, are rediscovering nature's contribution to identity (Wood *et al.,* 2010). Similarly, nature has become engrained in the cultural identity of some countries such as Bhutan (Zurick, 2006) and Costa Rica (Anglin, 2015), where NCP have been integrated into livelihoods and national economies.

NCP 18: Maintenance of Options

Preserving biodiversity is valuable in part because it maintains future options and potential for new discoveries. The loss of biodiversity reduces our options. Ehrlich (1992) compares biodiversity to a vast genetic library that has provided the very basis of our civilization—our crops, domestic animals and many of our medicines and industrial products but that "Innumerable potential new foods, drugs and useful products may yet be discovered—if we do not burn down the library first". (p.12). Preserving biodiversity preserves information embedded in genes and species. Information can provide global benefits because the results of new discoveries can be applied anywhere. We are losing many populations and species (see chapter 2.2) in taxonomic groups that have known value (Ceballos *et al.,* 2017) as well as those that have no know current value but may become important in the future. Measures of phylogenetic diversity, which give added weight to species with more unique genetic lineages, are also in decline (Faith *et al.,* 2018). Population extinctions and range contractions (an indicator of NCP18) are most severe in western North America, central Europe, India and Southeast Asia, south and central Australia, western and southern South America, and Northern and Southern Africa (Ceballos *et al.,* 2017).

2.3.5.4 Information gaps

Since the Millennium Ecosystem Assessment was published in 2005, a large amount of data have been collected on biodiversity, ecosystems, ecosystem services and more generally on the co-production and impact of social, environmental, and climate change upon them. Despite this progress, however, large information gaps remain in assessing the status and trends of NCP, and particularly their implications to the quality of life of different groups of people. Below are some of the major information gaps that should to be addressed going forward to improve future global assessments of NCP.

1. The extent of nature's contribution to good quality of life is not well understood for some NCP. The lack of understanding arises for several reasons. First, it is often hard to disentangle nature's contributions from other contributions. For example, though we have good data on status and trends of air quality across major cities in the world (WHO, 2016b), how changes in vegetation impact air quality in cities is less well understood and is currently a frontier of scientific investigation (Irga *et al.,* 2015; Janhäll, 2015). Second, understanding of key links between nature and impacts on good quality of life may be missing. For example, though we often have a good understanding of how changes in exposure affect disease incidence and impacts on human health, how changes in nature influence exposure is often complex and is poorly understood for some diseases (Bayles *et al.,* 2016). Exposure for vector-borne diseases depends on populations of vectors as well as how these vectors overlap with vulnerable populations of humans. Vector populations can depend on complex ecosystem interactions that give rise to unpredictable

increases or decreases in populations as a function of anthropogenic induced changes to ecosystems. Exposure also depends on human behavior and public health measures designed to reduce the vulnerability of human populations to disease.

2. Even where the extent of nature's contribution to good quality of life is well understood, there is often a lack of systematic data collection, or systematic documentation, on which to base a comprehensive global assessment. Much of the literature on non-material NCP involves detailed case studies of specific groups. This literature provides a wealth of information but studies typically differ in focus and methodology, and there is uneven coverage across regions, which makes it difficult to combine results into a systematic global assessment (Hernández-Morcillo *et al.,* 2013). For most NCP we lack systematic reporting on impacts of nature on good quality of life. Much of the natural science literature focuses on changes in ecosystems and biodiversity but does not report how these changes affects good quality of life. Much of the systematic data reporting on various aspects of good quality of life (such as income, livelihoods, health, and education) does not disentangle the impacts of nature on good quality of life from other impacts. It would be ideal to report quantitative measures of NCP in terms readily understood by various decision makers and the general public. While we have some measures of NCP reported in monetary terms, health terms, or other measures related to good quality of life, we lack systematic indicators that can be reported in a variety of easily understood metrics for many NCP.

3. A general issue in doing a comprehensive global assessment is the existing fragmented state of knowledge with lack of integration between social and natural sciences, and between western science and ILK. This assessment has emphasized the importance of including multiple viewpoints and sources of knowledge, but this has not been matched with an ability to effectively integrate multiple sources of knowledge into a systematic assessment. Different world views are hard to integrate in substantive ways. Doing so will require increased dialog across communities and agreement on how to be more systematic in knowledge generation and data collection.

4. The distribution across user groups of impacts of NCP on good quality of life are poorly documented. The original intent of this assessment was to report on impacts on good quality of life by major user groups by region. A typology of user groups was developed for this assessment, which involved differentiation based on livelihoods (subsistence gatherers, subsistence and commercial farmers, subsistence and commercial fishers, pastoralists, commercial ranchers, commercial foresters, mining and energy production, commercial and manufacturing), as well as residence location (rural, semi-urban, urban, coastal, inland, forest, grassland, desert, etc.). However, there has not been enough systematic study of impacts of NCP on good quality of life by user groups to date to allow such reporting. Many existing studies of NCP report on overall changes and do not break down impacts by user groups. In addition, though there is a rich literature on studies of particular groups and in particular places by anthropologists and other social scientists, as well as written material documenting ILK, but this information has not been systematically reported in a common framework that would allow for a comprehensive global assessment. Improvements in the ability to report on impacts by user groups would greatly improve the usefulness of future assessments.

5. Measuring trends in NCP requires having a time series of data measured in a consistent fashion. Consistent time series data exists for some aspects of some NCP but is lacking for many aspects of most NCP. For some environmental measures it is now possible to get consistent global data via remote sensing. However, many remote sensing data series begin with the satellite era, so that many of these time series are of fairly short duration. In contrast, measures of impact on good quality of life often require direct observation or survey work. Time series data exists for income, health and other measures of human well-being but typically does not report on the impact that nature has on good quality of life.

2.3.6 INTEGRATIVE SUMMARY AND CONCLUSIONS

Nature provides not only the basic elements needed for human survival, but also contributes material and non-material benefits that improve human well-being. Nature's contributions to people (NCP) include i) regulation processes that control the production of important elements for human well-being such as fresh air, potable water, shelter, and control of pests, ii) material goods such as the provisioning of food and energy resources, medicines, and construction materials, and iii) non-material value such as opportunities for learning, having experiences, and instilling a sense of identity. All these contributions rely to some extent on the biophysical properties of nature (e.g., ecosystems, populations, species) but also on human-nature interactions, which together define the co-production and outputs of NCP **(Figures 2.3.1, 2.3.2)**. For an NCP to positively impact quality of life it must be available, accessible, and valued.

The output of co-production for most of the regulating and non-material NCP have decreased since 1970. Only NCP that are related to the co-production of marketable goods show consistent increasing trends (i.e., materials, food and feed, and energy) **(Figure 2.3.3)**. Nevertheless, although the outputs of co-production have increased for most material NCP, the long-term ability of nature to continue producing these NCP has declined. For example, production of farmed fish has increased over the past 10 years, offsetting declines of about 10% in wild catch that reflect an estimated decrease of 6-30% in catch potential resulting from over-harvesting fish stocks. Potential NCP for ocean acidification regulation has remained stable or may have increased over the last few decades, as there was an increase in global marine primary production linked to multi-decadal variability in ocean climate (Chavez *et al.,* 2011), while 14 of 18 potential NCP have declined and others show contrasting trends across different proxies.

There is increasing recognition and awareness of the importance of NCP for a good quality of life. Declines in NCP have led to purposeful actions to try to arrest the decline, such as increasing amounts of protected areas, and efforts to maintain mangroves and coastal wetlands to provide protection against storm surge for coastal settlements and initiatives to protect 'blue carbon' stores in coastal ecosystems (Kennedy *et al.,* 2010). Nevertheless, overall trends continue downward for many NCP despite these actions, as they are outweighed by continued negative actions arising from population pressures, market forces, or system inertia.

In many circumstances there are trade-offs among NCP. For example, although an increment of cultivated areas has been shown to increase the provisioning of food and other materials important for people (e.g., natural fibers, ornamental flowers), it is also likely to reduce contributions of nature such as pollination by wild insects, pest control, and regulation of water quality. Agroecological means of producing food may reduce these trade-offs.

Tropical and subtropical regions seem to be suffering the most pronounced changes, as shown by the high number of NCP showing negative trends there. Deforestation, land conversion, and defaunation are the main factors behind the observed patterns. Differences in how trends in NCP affect quality of life across user groups are substantial, however, scarcity of data to date prevents a systematic review. These differences in impact arise because NCP accessibility and associated value are context dependent and vary with cultural preferences, knowledge, socioeconomic status, and geographical location as well as other drivers. Integration among natural and social science is needed to better assess the impact of NCP on quality of life. Also, further steps should be directed at reducing uncertainty of trends for both co-production and potential NCP. Taking into account likely trade-offs, it is critical to understand, integrate, and synthesize information across all NCP.
